MONARCH

Monarch Easy-opener Knife

No. 150

A Giant Pocket-knife

One of the best general-purpose knives that it is possible to produce. Absolutely perfect to the minutest detail. Blades made from the highest quality of finely tempered steel. Have heavy spring, yet are easy openers. Handsome stag handle, double German-silver bolsters and shield. Solid brass-lined and highly polished and finished throughout. Quality guaranteed. Monarch of all knives. Warranted to hold its edge.

Illustration exact size.

NO. 1

EDITORIALS

IN our last issue, page 968, under the general heading of "Retrospect," and referring to the particular work done by the Agricultural College at Guelph, Ontario, we inadvertently made the statement that said station was in charge of S. T. Pettit when we should have said Morley Pettit, a son of the former, who died a few years ago.

Our Cover Picture

EXCEPT that the hives are a little different in shape from most hives used in this country it is hard to imagine that the view shown on our cover is not an apiary situated in a young apple-orchard in some one of our northern States. As a matter of fact it is a picture of an apiary in Taquary, Brazil, sent us by Emil Shenk who, for the last three or four years, has been "ambulant" teacher of bee culture of the agricultural department of the federal government. Mr. Shenk writes that Brazilian bee culture is developing very nicely, but says he regrets that so little is said in regard to that country in GLEANINGS. He expects to send from time to time an article regarding conditions there.

The Bees at the Dismal Swamp

ACCORDING to the last report, these were coming on very nicely. While it was severely cold in and about Medina, the bees were flying at our Dismal Swamp yards.

The Virginia bees will be matched up against the bees in cellars and winter cases. If we can make a fair increase in the Virginia colonies that are too weak to winter at Medina, we shall feel abundantly satisfied. In this connection we may state that it is not our intention to go in for as heavy increase as we did in Florida last winter, for we shall do considerable in queen-rearing during March and April in the Dismal Swamp.

The editor of GLEANINGS expects to make a trip to the Dismal Swamp about the 15th of January. On his return he will give a

report of what he finds from a direct inspection of every colony wintered; and when we say *colony* we mean hives with bees in them. These hives, when they went down originally, had only two, three, four, or five frames of bees—bees that had been used for supplying pound packages up to the very last minute at Medina, and which were in no condition to winter, either indoors or outdoors. We have always observed that colonies that have been used for filling orders for nuclei or queens clear up to the time of going into winter quarters are either very weak in the spring or die outright. Our Dismal Swamp experiments are to determine whether we can utilize these cripples, so to speak, and make something useful out of them next spring.

A Proposed State-wide Foul-brood Law for Idaho

As a general thing a county foul-brood law, while it is better than nothing by a long way, comes far short of a State law for getting the best results. In every State where a county law is in effect the defects of the system have been so marked that, so far as we know, these county laws have either been replaced by laws State-wide in their application or are on their way to such replacement.

Idaho has probably the best county law of any of the States in the Union; but its defects have been already noticed; and the Idaho Honey-producers' Association, the most influential organization in the State, with its headquarters at Idaho Falls, Ida., expects to present to the Idaho legislature a draft of a new State-wide bill that incorporates some of the best features in other foul-brood laws adopted by the various States.

There are fair prospects that this bill can be passed; but it will need the united support of *all* the beekeepers of Idaho. Those of our subscribers who desire to cooperate are requested to get in touch with

the secretary of the Idaho Honey-producers' Association, Mr. F. C. Bowman, whose post-office is Idaho Falls, Ida. Prompt action will be necessary, as the legislature meets very soon.

A Variety of Experiments in Wintering being Carried on at Medina

This winter we are carrying on a variety of experiments in wintering our bees. Part are wintered indoors and part outdoors. The former are in two different cellars. In one (the warehouse cellar) the temperature ranges from 40 to 45, and in the other (the machine-shop cellar) from 45 to 60. The temperature of these cellars is somewhat dependent on the temperature outside, and hence the variation. Each cellar of bees is inspected daily to ascertain the purity of the atmosphere, the temperature, and the condition of the bees so far as it can be ascertained by a squint with an electric lamp at the entrance of several of the hives. In order to determine the temperature, tested mercurial thermometers are used. We secured the best we could find, and then placed a set of them outdoors for a few days, and then inside, and those that recorded exactly alike were selected, and placed in various portions of the cellar—some near the floor, some midway, and some near the ceiling. We note that the temperature in the upper part of the cellar is always higher than when near the floor by three or four degrees.

So far, Dec. 30, the bees are wintering nicely in both cellars, with the difference a little in favor of the cooler cellar. A few days ago we brought in one yard of bees containing our finest breeding stock, with a team and bobsleds. These bees were housed in double-walled hives; but as the weather had turned very cold we desired to give these bees every possible chance, and so we brought them home and housed them in the cooler cellar. We did the same thing last year after the weather had turned severely cold, and there was good sleighing. The results were highly satisfactory. The best time in all the world to move bees from out-yards to the home cellars is when there is good sleighing. One pair of common runners for going through the woods after bees are better than a pair of bobs for moving bees. While the former will skid a little more, they will go over bumps easier.

OUTDOOR WINTERING IN QUADRUPLE WINTER CASES AND IN SINGLE INDIVIDUAL DOUBLE-WALLED HIVES.

As previously reported, we are testing out the ordinary individual double-walled pack-

ed hives alongside of hives with quadruple winter cases of the Holtermann type in the same yard. While these big cases are more expensive per colony, the bees in them are certainly showing up well. During the very coldest part of the winter, when the mercury plays around zero, with a high wind, the bees look very comfortable, and no wonder, for there are four hives in the case placed close together and with ten inches of packing all around. Very cold weather does not seem to affect the size of the clusters as it does in single hives.

Two colonies in these cases diagonally opposite each other are provided with absorbing packing above, while the two other colonies also diagonally* opposite have a sheet of glass for the purpose of observation, laid on top of the hives. While the latter does not make exactly what would be called top sealing, it does prevent to a great extent the upward escape of moisture. A little of it can pass out under the sides or edges, because the glass covers are not sealed down. So far colonies with glass covers are showing up very much better than where there is a free and unobstructed upward ventilation through the packing material. The packing over the hives where the glass is not used and where the moisture and heat can pass upward is a little damp; and this damp packing seems to have the effect of driving the bees down lower on the frames. We called Mr. Holtermann's attention to this when he was here. The showing in favor of the colonies under glass was so marked that he thought the other colonies must have been considerably weaker; but our apiarist assured him that all four colonies were of as nearly equal strength as we could get them.

Whether the colonies under glass will continue to show up as favorably in the spring remains to be seen.

Special Numbers for 1915

WE wish to call especial attention at this time to the list of special numbers announced on the inside cover page of the December 1st issue. It will be observed that we have planned for only four numbers, our idea being that, in having a smaller number, we could devote a little more time to the subject-matter and secure better material, perhaps. However, since announcing this list so much material has come in in regard to swamp beekeeping that it is probable we shall have one more number, perhaps the September 1st issue, on this subject.

* The object of this is to give the same exposure to the pair side by side.

It is always a problem to know just what subjects to select. We always have more requests for special numbers than we can handle. For instance, in making our plans for 1915 we had some thirty different subjects suggested by beekeepers, practically all of which would be suitable for special numbers. We can truthfully add the words "By request" to each subject that we finally selected, for in matters of this kind we prefer to act in accordance with the wishes of our readers themselves.

The February 1st issue, "Experiences of Prominent Beekeepers," is the first special number for the year. Our plans for the material going into this number are about complete. We expect to present a splendid outlay of advice from beekeepers of the professional class to those of the amateur class.

The April 1st number, the special theme of which is the life and teachings of Moses Quinby, is partially under way. What a pioneer he was! The amount of original study that he did is surprising. Working independently he went on far ahead of his day. If any of our readers have been particularly benefited by the teachings of Mr. Quinby we hope that they will write us regarding the matter, and we shall be glad to have some reference made to it in this number.

The August 1st issue, as announced, is to be the beginning of what we hope will be the most complete and elaborate bee botany ever offered to the public. We have already made some extensive plans for this number. John H. Lovell, an expert botanist and photographer, is going to make an elaborate contribution. It is hardly possible to collect too much material along this line, however, and therefore we are going to make this proposition: For a good detail photograph of a valuable honey-plant, new or old, together with a little description giving the time of blossoming approximately, quality of honey, importance of the plant, and any other interesting features, we will pay \$1.00 to \$5.00 in cash, provided the photograph is one that we can reproduce.

Where it is possible the photograph should be natural size, and should include both leaves and flowers; but do not use too many of either. For colored flowers (all that are not white) orthochromatic plates are desirable, and a ray filter will bring out the relative value of orange and blue flowers.

All pictures not accepted will be returned if stamps for this purpose are enclosed. You need not be a beekeeper nor even a subscriber to GLEANINGS to accept this offer.

It is open to every one. Photographs 5 x 7 are preferred. Snapshots and photographs taken with small kodaks would probably not be acceptable unless very clear or of rare flowers. Photographs of large plants and trees show the flowers very indistinctly, and it is pictures of *flowers* that are wanted. In some cases, however, it may be desirable to send also a photograph of the entire plant.

There are some exceptions to the foregoing; but what we want primarily is a photograph so clear and sharp that one not acquainted with the plant could recognize it from the picture if he should see it. The lens must be "stopped down" in order to make the picture sharp and full of detail; and this means that the exposure, which must be short to prevent blurring caused by any movement of the leaves or blossoms, must be made in a very good light in order to secure the depth necessary. The negative must be printed on a glossy black and white paper; and the print, in order to reproduce well, should be just a *trifle* darker than would be necessary from a photographic standpoint. Here is a chance for beekeepers having cameras to make some money on the side; and, incidentally, to contribute to a much needed cause.

Since the publication of our booklet, "The Use of Honey in Cooking," a good many have written us telling of splendid new recipes that they would like to send us whenever we get ready to publish a special number on the subject. We wish to use a large number of recipes in this special number of October 1, "Honey for Cooking and for the Table," also "Honey as a Remedy." For any recipe which has not been published before, and which we can use, we shall be glad to pay \$1.00. Therefore, if you have a good recipe which you have tried and *know* is good, and if you have use for an extra dollar, just send us the recipe in question.

In reference to the material used along the line of "Honey as a Remedy," perhaps we should add here this word of caution: Sometimes honey is recommended as a cure for very serious diseases. While we should be glad to publish any such that are sent in good faith, we feel that it would be best, in case of serious diseases, to have the name of at least one reputable physician who has used the preparation containing honey for the disease in question. This will go a long way toward preventing the publication of what might be called "hearsay evidence." The remedy might not and probably would not be harmful, even if it were of no value; but honey is sufficiently valuable for ointment in case of skin trouble, for colds,

including sore throat, hoarseness, etc., to make superfluous any attempt to prove it a cure-all.

Boiled Honey Not Suitable for a Queen-cage Candy, and Why

A YEAR or so ago the postal authorities at Washington required a certificate of inspection with every package of queens that went out through the mails, or a copy of an affidavit showing that the breeder boiled thoroughly all the honey in the queen-cage candy. To boil the honey was a nice procedure, but it seemed like a wise precaution, and we, like many other queen-breeders, not only furnished a certificate of inspection with every package of queens, but boiled the honey also.

We noticed that, for some reason, shortly after, queens would not go as far in the ordinary mailing-cages as they had done formerly. We observed also that we had to replace more shipments than formerly; but at the time we did not connect up cause and effect. We discovered, also, that it was practically impossible to send queens to foreign countries where hitherto we had sent them without any great difficulty. We changed the sugar; we altered the size of the cage; we modified the form of the cage. We put in water-bottles, thinking the bees needed a drink on the way. We gave them chunks of comb honey along with the queen candy; but, no matter what we did, the results were almost the same.

We discovered, also, that when we began to ship bees in pound packages this spring and summer they did not go through to their destination as well as they formerly did. We perfected the water-bottle, and that helped a great deal. We added a can of sugar syrup in addition to the can of water, and that helped, but continued to use the old queen-cage candy as before; but still the bees did not travel through in pound packages nor in mailing-cages as well as formerly. We were at our wits' end.

Finally we went back to the old style of export mailing-cage we used years ago that would deliver about 50 per cent of the queens alive to Australia. This failed as did the others. Then we began to think that possibly in some of the foreign countries the packages of mail, to prevent the spread of disease, were fumigated. But this did not explain the fact that in many cases the bees on arrival at destination had died of dysentery. Then we began to think it might be the wire cloth; but it could not be that, because there were some cases where no wire cloth was used, and yet the bees died just the same.

We began to get a clue to all our trouble when our Mr. Brown reported that there was one lot of bees that showed dysentery very strongly in the last car that went to the Dismal Swamp, Virginia, while other bees from other yards of equal strength showed no trouble. An examination of the record showed that the stained hives came from the Ault apiary. Now, the Ault bees had been fed with boiled Porto Rican honey to prevent any possible danger of disease. But the bees, apparently, did not like boiled honey, so we began to feed it later without boiling. But a great deal of boiled honey* had been fed just the same. The significant fact was that the Ault bees in the second car showed signs of dysentery at the end of the journey, when all the others showed no such symptoms. Finally it dawned upon us that the dysentery in the Ault bees in the earload and the dysentery in the pound packages of bees and in the bees in the mailing cages was due to a common cause, viz., boiled honey. The fact that a number of these shipments showed up dysentery, and that many others died without showing any symptoms, began to make us believe that the postal regulations, requiring the honey to be boiled, issued with benevolent intentions toward the beekeeping industry, were responsible for our trouble. Had not those authorities granted us the alternative of using an inspector's certificate in lieu of a statement that the honey had been boiled, the ruling would have come very near barring bees and queens from the mails.

It is possible that invert sugar might be used in place of honey in the making of a Scholz or Good candy. As invert sugar is similar to honey, there is no reason why it could not be used, providing, of course, that the substitute does not cause dysentery as does boiled honey. It is possible, and probable, on the other hand, that we may be able to use the "fondant" (made of glucose and cane sugar) praised so highly by our Massachusetts friends. But if neither fondant nor any other kind of sugar will answer, it is still permissible to use the old bee-candy such as we formerly used, made by mixing powdered sugar and raw unboiled honey into a stiff dough, provided, of course, that every package of bees is sent out with a copy of a certificate of inspection from a duly authorized inspector.

It is too late now to try out the whole proposition of mailing-cages and pound

* In boiling honey to kill possible bee-disease germs it is very easy to burn or scorch a little of it if it is not kept thoroughly stirred. Years ago A. I. Root found that a slightly scorched honey fed to bees for a winter food was almost sure to bring on dysentery, and in practically all cases it killed the bees outright before the winter was half over.

packages this season with either one of the substitute foods mentioned; but the reader may rest assured that we will give them a thorough trial again next summer.

Of course it is by no means proven yet that boiled honey has been the source of our trouble; but the indications point that way very strongly. It is certainly worth investigating, as our replace shipments by mail and express last year cost us hundreds of dollars.

A Serious Situation in Colorado; how the Spraying of Fruit-trees is Tending to Paralyze the Beekeeping Industry on the Western Slope

MORE and more it is becoming apparent that the spraying of fruit-trees in Colorado (or rather, perhaps, the spray falling on cover crops beneath) is destroying bees in such a wholesale manner that, unless something is done, beekeepers will be compelled to give up honey production entirely, or move their bees, if they have any left, to localities remote from any orchard. Some of the orchardists feel that bees are their best friends, and that they cannot afford to adopt any policy or practice that will cause their general removal. If all were like them the difficulty would be solved. More and more, facts are beginning to pile up, however, showing that thousands of colonies are either destroyed outright, or at least are so weakened that they are practically worthless. Unless something can be done it is estimated that something in the neighborhood of 5000 colonies (or as many as may be left) will have to be removed from the vicinity of the orchards in Western Colorado.

The experience of the last year or two in that State leaves no room for doubt now that the arsenites of the ordinary strength used for killing the codling moth will kill bees when the solutions containing them fall on the clover-blossoms beneath. Notwithstanding that, there is some testimony that goes to show that the same *spray on the trees* themselves is not necessarily destructive. In our last issue, Mr. J. A. Green, page 794, gives some evidence showing that the wholesale destruction of bees as the result of spraying can scarcely be questioned. On the other hand, Mr. Woodworth, on page 987, introduces some other testimony to the contrary. Fortunately this conflict of opinion can be easily explained.

A few days ago our Mr. J. G. Brown, one of the Colorado sufferers, and who came to Medina to work for the A. I. Root Co. because his business was ruined by the spraying of fruit-trees, offered an explana-

tion. He says that the spraying of fruit-trees, even when in bloom, when there are no cover crops or clovers beneath the trees, does not necessarily poison bees. So far he agrees with Mr. Woodworth. The orchardists of Colorado, acting on the advice of their entomologist, Prof. C. P. Gillette, have been in the habit of spraying before and after the trees are in full bloom. Very frequently such spraying will be applied before the petals begin to fall. Against such spraying there is little complaint; but when the orchardist grows a cover crop to fertilize the soil of the orchard, the spraying liquids fall down on the clover-blossoms, which are in just the right shape to catch the full strength of the poison. It does not matter whether the trees are in bloom or not. The sprays fall down on the clovers that *are* in bloom, the bees visit them, and are destroyed by the thousands. One yard of Mr. Brown's bees is practically ruined. Many colonies were killed outright, and others were so weakened that he could not do any thing with them. One of his neighbors, an orchardist, stoutly protested that the sprays that fall on the cover crop did not kill bees, saying that the cause was to be accounted for in other ways. He had, he said, a few bees in his orchard, and these bees were all right. Mr. Brown told him that he must be mistaken; and to convince him of his mistake the two examined the bees that were supposed to be "all right," with the result that they found them nearly all dead. Mr. Orchardist was convinced.

Many of the fruit-growers acknowledge that the sprays that fall on these cover crops kill bees; and so far as *they* are concerned they will do any thing that is reasonable to save the lives of the bees, for bees *they must* have. Other orchardists are not willing to make this admission. Unless all the fruit-growers will co-operate, bees will be destroyed by the thousands, and a big industry will be practically paralyzed.

The question will be raised, "Why have we not heard of this wholesale destruction of bees in Colorado before?" Mr. Brown explains it by saying that green manuring—that is, growing cover crops beneath the trees—to renew the soil is a comparatively recent practice. Orchardists over nearly all the country have learned that one of the simplest and most economical ways of doing this is to plow under a crop of some sort. Crimson clover has been used largely for the purpose. In Colorado red clover is used almost entirely; but it happens that it is in full bloom before the spraying season is over. The poisonous liquids that fall from the trees drop on the clover-blossoms, then

the bees get them. As these clovers furnish nectar when there is nothing else, bees are killed by the thousands.* Sometimes the spraying is applied on the trees before all the petals have fallen; but if no more nectar is yielded, no harm is done to the bees. So the spraying of orchards *before* cover crops were used, did little or no harm to the beekeeping industry. The damage occurred only when there was ignorant spraying, the poison being applied when the blossoms were full of nectar. But such spraying has practically gone out of vogue. But the recent introduction of green manuring in the State has brought on a new and serious problem, because the bees, naturally enough, will help themselves to the nectar in clover-blossoms.

The only remedy seems to be in cutting the clover just before it comes into bloom, or turning it under. The best authorities on soil culture recommend plowing the clover of cover crops under *before* it blooms, because at that stage of growth it makes a better fertilizer. Whether all the orchardists can be induced to see that this would be to their advantage as well as that of the beekeepers is doubtful. For that reason remedial legislation will have to be enacted, for there will always be a few who will persistently remain ignorant, for no ignorance is so dense as prejudice. There will always be some who imagine that bees are stealing something from their fruit-trees, and that the bees are of no use to them. Considering the fact that a large number of intelligent fruit-growers will not wish to destroy their best friends, the bees, and will favor suitable legislation, and the further fact that *all* the beekeepers will unite with them in asking for a law that will protect their common interests, it is to be presumed that the legislature of Colorado will, at its next session, provide the needed relief. If it does not, we are informed that something like 5000 colonies on a conservative estimate will have to be moved out of the vicinity of the orchards on the western slope; and this will cut down the fruit crop over a large section of the State, and at the same time have a tendency to overcrowd other locations in Colorado that are already overcrowded with bees.

Later.—Since writing the foregoing the following extract from a paper read at the Montrose Co. Beekeepers' Association meeting has been sent us. The author of the paper, O. C. Skinner, of Montrose, Col., is the Speaker of the House of Representa-

tives of Colorado. Here is what he has to say confirming to a great extent what we have already said above:

The beekeepers of Colorado, and especially those located within the fruit belts and on the western slope, have been heavy losers this year on account of the poisoning of bees and larvæ with spray poisons.

The new Colorado law, passed by the last General Assembly, prohibits the spraying of fruit-trees "while in full bloom," and it was thought that this would sufficiently protect the beekeepers from this danger; but in place of the regular fruit-blossom-spray danger, another has arisen to plague the honey-gatherers.

Many orchardists, especially on the western slope, which is an extensive fruit section, have begun to plant a cover crop under the trees in order to fertilize, and to protect the surface from sun and wind and drouth. In that locality the cover crop usually chosen is red clover, and the danger now developed is that this clover blooms long and vigorously, after the trees have shed their blossoms, and when the law as it now reads will allow spraying, for the trees are not "in full bloom."

The result is that the beekeepers in the heavily fruit-growing sections have been almost put out of business, some having not only lost all the honey crop, and failed entirely on increase, but also lost many stands of bees from dwindling.

Around Montrose the loss was very heavy because there is a lot of red clover used as cover crop there. The spray mixture falls on the blossoms of the clover; and while it is generally supposed that bees do not work extensively on red clover, yet in the season of 1914 they worked enough to make the honey business almost a failure in that locality. It is suggested that the year 1914 was conducive to the small growth of the flower of red clover, making it easily worked on by bees, and therefore more to be dreaded than in ordinary years, but that is not proven.

The effect of the spray poison is quickly apparent, the bees hopping along the ground, unable to rise, and those which do yet fly exuding a yellowish or brownish watery mixture, which can readily be seen on the ground and on the hives. On crushing the dead bees, this yellow excretion will be seen to exude.

Among the orchardists who were driven from the orchards of that locality are J. C. Mathews, who had to move two apiaries; J. J. Corbut, Will Corbut, A. B. Clement, and O. C. Skinner; while the Allen Bros. and J. G. Brown held their bees in the orchards, and especially in the case of the former, an entire loss of crop and a heavy loss of bees resulted.

In any yard located in the fruit belt, in the early morning, and just after the bees had begun to fly lively, the ground in front of the hives would be literally covered with sick bees trying to fly, or crawling along the ground, while at any time of day the dead bees could be found all about.

J. C. Mathews got little or no return from the bees he moved out of the orchards. The Corbuts had about the same results. A. B. Clement got no returns from those he moved out, but saved the bees. O. C. Skinner moved his apiary into two new ones, and got about a quarter of a crop of honey from one apiary and a fair number of swarms; but from 142 moved later to another location he got no honey whatever; had no swarms at all, and the original 142 colonies are now reduced to 114, with a fair chance that there will not be over 100 left in the spring. This latter heavy loss was probably due to having the apiary, as located before moving, directly alongside a clover-field under fruit-trees, where the bees worked constantly. It seems that the bees were so reduced before moving, and so discouraged, that they did not even build up properly for winter.

* The fruit-men know that these crops should be plowed under before they come into bloom; and about the only reason why they don't do it is because they are too busy with their spraying.

Dr. C. C. Miller

STRAY STRAWS

Marengo, Ill.

EXPERIMENTS reported p. 987 seem to show that poison which kills codling moth doesn't hurt bees. The proof is negative, but I suppose it will have to stand unless some one comes along with positive proof that in another case it does kill bees. [See editorial elsewhere.—Ed.]

CONSIDERING the pages and pages that have been written about the trouble with candy and syrup, I wonder if we won't some day settle down upon it that the wise thing is for each beekeeper, if he can't have on hand a stock of sealed combs, to have at least enough candied honey, "own make," constantly on hand to meet all emergencies.

G. M. DOOLITTLE 'fesses, p. 973, that he makes mistakes and failures. Thank you—thank you kindly, Bro. Doolittle; glad to have company. Then Editor Root admits that he doesn't know every thing by appealing for "light on this matter" of feeding honey vs. sugar, p. 963. Really, one great beauty of beekeeping is that you never get to the end—always something more to learn.

"LIGHT fluffy snow" to close entrances when cellaring bees, p. 963. Good! Wet rags when no snow. Better than either, the way mine were carried in this year—just picked up and carried in with open entrances, and no veils. That should be possible at 40 degrees or lower, when bees have flown two or three days previously. Mine went in the same day as yours, Dec. 8, at 26 degrees.

GEORGE SHIBER, you use the Doolittle plan to shake bees off extracting-combs on the ground, p. 988. With heavy combs I wonder if you wouldn't find it a little quicker and a good deal easier to try the pendulum plan. Take hold of one end of the top-bar; swing up the comb in front of you with the bottom-bar pointing forward, then let the other end of the top-bar strike the ground with comb in such position that the corner of the frame on the ground and the diagonally opposite corner shall be in a vertical line.

ONCE when I was at Medina a colony with American foul brood was at night thrown into a furnace, and hive, combs, bees, every thing, burned up. That's a safe treatment. Yet you would hardly advise it, Mr. Editor, nowadays, even for a careless beekeeper, if he had a dozen affected colonies. You would certainly save the bees, and probably the hive and the healthy brood.

You think, p. 882, that if you had European foul brood you'd destroy the combs. Likely enough, just as at first you destroyed bees in cases of American foul brood. But I feel sure you would learn that it is just as safe to save combs with European foul brood as it is to save bees with American foul brood. Moreover, please remember that with me European foul brood came back as much with shaking as with dequeening. Say—isn't it a bit ungrateful in you, Mr. Editor, to go back on me for advocating the saving of combs in European foul brood when I began it just to please you? [No, we did not go back on you. We stated that, with your knowledge and your environment, we would do exactly as you are doing. We only thought it was a little dangerous to tell the general public that it was safe to use the old combs over again that have been affected with European foul brood. While it is true we originally promulgated the idea that such combs could be saved (and we believe they can be in the hands of an expert), yet we, as publishers of GLEANINGS, are dealing with the great masses who are not experts; hence our advice to burn the combs as a general proposition. While we believe *we* can save the combs of European foul brood, yet on the other hand we are selling colonies in nuclei to beekeepers all over the United States; and it would be unwise for us to send out any combs, even after they have been cleaned up by the bees, that have once contained European foul brood, and we would be severely censured if we did. You yourself would follow our policy.]

We realize the fact that it is a little difficult to be entirely consistent clear through unless we take into consideration the parties with whom we are dealing. It does look as if we were reversing our policy to advocate burning the combs of European foul brood when it was we who made public the Alexander treatment and published many articles indorsing it, showing that the combs of European foul brood could be saved. If we had it to do over again we would do it again, because in so doing we would save experts thousands of dollars. If we were in the business of honey production only and were not shipping bees or colonies, we would burn no combs containing only European foul brood, because we believe our knowledge and experience would enable us to do just as you have done. There, now, doctor, have we made ourselves clear?—Ed.]

BEEKEEPING IN CALIFORNIA

P. C. Chadwick, Redlands, Cal.

The loquat and eucalyptus are furnishing the bees a source from which to get an encouraging amount of nectar and pollen for winter encouragement.

A heavy rain has fallen during the past twenty-four hours (Dec. 12). This will insure the early-blooming flowers sufficient moisture to bring them forth on time and in abundance. Early breeding is all but assured. This, with the already prosperous condition of colonies, will have a tendency to increase the size of the crop, even with a light flow.

Certain blooming periods are given in "Honey-plants of California," as applied to the pepper-trees. Except that they begin blooming in early spring and continue until winter, they have no distinct blooming period. There are several trees near my home that are blooming now, Dec. 12. I do not mean to say, however, that every tree blooms constantly from early spring, but there are trees in bloom during that period.

A word of warning to those who are contemplating a move to this State to take up the bee business: If you are doing even fairly well where you are, better stay. There are hundreds contemplating the move who are only doomed to disappointment, at least for a time. Conditions are so different from those in the East that one must become acquainted with the ways of the West before it is possible to make a success of the business here. There are many Eastern beekeepers here who have made the assertion to the writer that, if they were now in the East with the experience they have gained in the West, they could make the business pay more dollars there than here. But all agree that they are willing to do with fewer dollars for the sake of the climate. But climate will not keep us all, and the real problems must first be solved by those acquainted with conditions here before a full measure of success can be realized.

Mr. G. H. R., page 926, Dec. 1, your explanation has cleared matters greatly, as I see it. The fact that the colony of which you speak drew out six sheets of foundation with but one quart of syrup does not prove the syrup was wholly responsible for the six sheets of foundation having been drawn.

I have solved it like this: The syrup caused the bees to draw the foundation. That is what was done in this case, and not merely the addition of wax to the foundation. The ordinary medium-brood foundation is much heavier than is utilized for the base of the comb; but the cells are drawn to a greater or less degree from the foundation without the addition of a single wax scale by the bees pulling up the surplus wax into cell formation. I am of the opinion that has been the case with your foreman's experiment. Take a sheet of light, medium, and heavy brood foundation, and measure the base before placing in the hive. After they are drawn, examine the base and you will find that it is much thinner than when placed on the hive. Take the same sheets when drawn from 1-16 to $\frac{1}{4}$ inch and you will find the cell construction the same color as the base. There is little foundation drawn by bees the base of which is not reduced before the cells are completed. [See article by R. F. Holtermann on this subject, page 13.—Ed.]

Whether the editor of the *Beekeepers' Review* was alluding to the California State Association or some other in the November issue, I am not able to say. However, he came near hitting the nail squarely on the head so far as this State is concerned. It seems to me the selfish attitude we have assumed in this is little less than inconsistent. I am not a member of the National, but expect to return to it very shortly. The reason I am at this time not a member is that I was influenced by a prominent member of the California State Association to hold allegiance to our own association only. I see by the actions of our own association in its efforts to organize county clubs to enhance the value of the State association that there must be strength in organization. So I have come to the conclusion that, if there is strength in a State association, there must of necessity be a greater strength in the National; and it is my opinion that we shall soon see the California State back in the fold of the National. It should be. There is no valid reason why it should not be. I was told, when persuaded to leave the National, that we needed the money to promote our own association. Naturally I was interested in our own organization, and decided to obey suggestions. Now I see where I was weak, not only in paying my

BEEKEEPING AMONG THE ROCKIES

Wesley Foster, Boulder, Colorado.

With the winter setting in early in the east and central States, it has been the opposite here in the West. We had no snow or cold weather to speak of until early in December. Bees have had a favorable season so far; and with a fair quality of stores there should not be much loss in wintering.

With the postoffice officials giving orders for more care in handling packages it may not be long until honey may be sent safely by parcel post. I was told by one of our postoffice clerks that honey is a liquid while eggs are not. This being the postoffice ruling, he would not accept honey for shipment by parcel post unless there was absorbent wrapping enough around the package to absorb all the honey in case the package should be broken and the honey leak out. I think that, with the effort the Postoffice Department is making to extend parcel post, a few more disastrous leaks of honey will have as beneficial an effect on handling parcel-post matter as it will detrimental. Until the department will accept and carry the same class of package goods as the express companies it will not fulfill its rightful sphere.

WHAT TO DO WITH COMB HONEY.

I have had some discussion with beekeepers as to the advisability of selling cull honey on the market at all. Some take the position that this honey should be fed back to the bees or rendered. Cull comb honey weighs about 16 pounds net to the 24-section case, and sells locally at \$1.75 to \$2.00 a case. It retails for 10 cents a section, or three for 25 cents. There is no doubt that it tends to lower the price of the higher grades. On the other hand, there are a great many people who will buy this honey when they would go without if they had to pay 15 to 20 cents for a section. There is an increasing amount of fruit being sold in bulk. Peaches are being sold in bushel baskets instead of small baskets and boxes, and it is because they are cheaper. The expensive methods of packing and marketing produce do not appeal to all buyers. Having on hand about 35 supers of unfinished comb honey weighing about 10 lbs. net to the case (deducting the weight of the section), I started selling it locally by weight at 10 cts. a pound, and it is the best "come again" trade-getter that I have seen

for some time. It can be carried home either in the sections, or broken out of the sections and carried home in a pail.

STAMPING THE WEIGHTS ON COMB HONEY.

The point raised by Mr. Burnett, page 922, Dec. 1, regarding incorrect stamping of the weight on sections of honey, is a good one. In Colorado we have been packing our honey in three grades, with a minimum weight for each grade. When we have a section of honey that will not grade more than No. 2 on account of a few unsealed cells the weight is stamped "Net weight not less than 10 ounces." This section in many cases may weigh 12, 13, or 14 ounces net. All the sections in a case are stamped the same net weight, but they may not weigh the same, although the most careful packers keep sections of uniform weight together in a case. A heavy-weight case of No. 2 comb honey may weigh 15 or 16 ounces net weight; but if it is No. 2 on account of finish or color, each section is stamped "Net weight not less than 10 ounces." This statement on the section may be true; but it is not accurate, and does not help the sale of the honey.

The rubber stamps that the writer has seen do not have the lettering of the net-weight minimum large enough; and instead of printing it this way, "Net weight not less than 12½ oz.," it should be printed this way: "Net weight not less than twelve and one-half ounces." I would think further that the half-ounce weight should be discontinued, and only even-ounce weights used.

With a good set of rubber stamps with the lettering large enough it is not difficult to do rapid and neat stamping. It is not a difficult matter to get the stamp printing straight across the top of the section, but I have seen a lot of twisted work done.

Continued from previous page

local dues without question, but in failing to stay with the National. There is no class of producers in our land who are as timid about paying out a little money for organization and advertising as the beekeeping. The difference in the amount of cash that comes into our hands marketing our produce as we do, from what it would be with constant and judicious advertising, is so great that we would be astonished at the results of advertising.

NOTES FROM CANADA

J. L. Byer, Markham, Ontario

The common dandelion is one of the hardiest plants in our latitude. About Nov. 18 we had a cold snap for two days in which the thermometer dropped to zero for a few hours. Early in December, on a mild but by no means warm day I noticed quite a few dandelions in full bloom on a southern hillside. There had been no snow, and I was surprised to find the bloom withstanding the recent zero temperature.

I am interested in the discussion regarding the comparative value of late swamp pasturage as compared with feeding honey or sugar to build up small colonies in good condition for wintering. One factor has not been mentioned, which would have a great bearing on the success of such experiments here in Ontario. The colonies fed in early fall on good sugar syrup would be almost sure to winter if given any ordinary protection, no matter how severe a season might follow. On the other hand, experience has shown that, taking one year with another, late fall honey such as aster and goldenrod, are very uncertain provisions indeed in so far as the wintering of the colonies having this honey is concerned; consequently there is no question but that it will pay us best, when occasion so requires, to depend upon the artificial feeding instead of moving to fall pasture. By fall pasture I have in mind any honey coming in after September in our locality. Buckwheat with us has generally proven a good wintering food; and when it has seemed to give trouble, generally the presence of some honey-dew would explain matters.

When sending notes for the Dec. 1st issue I mentioned the fact that October and early November were unusually mild for our locality. As usual, one extreme follows another, as the saying goes, and we have had, since about Nov. 12, steady cold weather. To-night, Dec. 14, the thermometer is standing at 2 below zero, and a heavy wind is blowing from the northwest. Bees have had no flight to speak of since the last of October, which is quite different from the record of the past two years when flights occurred in early December.

Naturally this means a longer confinement for the bees wintering outdoors, assuming that spring flights come about the same time

as other years. This may or may not mean quite a difference in wintering prospects, especially where the bees are wintering on natural stores of quality none too good, as a late fall flight often means the saving of many colonies that would otherwise suffer if the flight were not available. We are especially concerned about the large apiary wintering on stores, much of which consists of aster honey gathered in September. Not having a late cleansing flight I would not be surprised if the loss might be heavy. But there is no use in borrowing trouble; and, for all one knows, perhaps we may yet get a "January thaw."

LOCALITY, AND HOW IT AFFECTS THE FLOW OF BUCKWHEAT.

The much abused term "locality," after all, does have a great deal to do in explaining differences that are otherwise unexplainable. For instance, if a beekeeper would have told me that buckwheat yields in the morning, then stops and again yields toward evening, if I did not know my informant well, would either question his veracity or think his powers of observation were out joint. But on page 834, Nov. 1, the editor says that this is a fact in New York. Of course I believe the statement, even when I am positive that bees never get nectar from buckwheat here in Ontario after it stops yielding about noon, as it always does with us, except on damp warm days when the sun is partially obscured, when it may yield till 3 or 4 P. M. It is all a question of locality, and the vagaries of this same factor should make us a bit more charitable sometimes, instead of questioning too much the experience of some one which seems so diametrically opposed to our experience as to be unbelievable. [In this "locality" bees never work on buckwheat more than two or three hours in the morning, and again an hour or two in the late afternoon. The explanation is, too many bees for the amount of flora. In the State of New York, if we remember correctly, there were places where the conditions were about the same as those you report; but in most places the rule seemed to be about the same as in and near Medina.—ED.]

Owing to rural routes being established in our section, my postoffice is now Markham instead of Mount Joy. Those writing me will kindly note the change.

CONVERSATIONS WITH DOOLITTLE

At Borodino, New York.

CARE OF COMB HONEY.

"Will you tell us something about the care of comb honey—how to look after it when taken from the hive, grade it, etc.? You may have written something of this in the past; but remember that the constantly increasing number of readers of GLEANINGS do not all have access to the volumes published years ago."

Allow me to say at the outset that it should never be forgotten that honey of quality, and in any of the popular packages, will constantly command a good price, far above that of poor quality, put up in a slipshod way. The better grade tempts every eye, thus producing a longing which makes a steady customer. I was once told that no product of field and farm varies so much in price as comb honey. On asking why, I learned: "It only requires to be put up attractively to create a demand for all that can be produced in America." While I would take this statement with allowance, I consider that there is much truth in it. Comb honey has the preference for table use at the present time; and if we would cater to the public we must produce that article in the most attractive shape.

This is arrived at by growth. In 1850 to '55 the smallest package of comb honey marketed as the bees stored it in this locality was a fifteen-pound box. By 1862 a six-pound box having glass on two sides came into quite general use. The year 1870 found the beekeepers using boxes holding three and four pounds with four glass sides and tin for corner posts, only the tops and bottoms being of wood from $\frac{3}{8}$ to $\frac{1}{4}$ inch thick. These were very attractive, as they not only showed the nice white face side of the comb, but told at a glance at the ends of the combs the coloring of the honey, which was a fair index of the quality and source of the sweets inside. However, the beekeepers were not yet satisfied; for after these came the sections which were then two and three pound "boxes," and these gradually gave place to the one-pound section.

Comb honey should be taken from the hive as soon as it is finished and fully capped over, or as soon thereafter as possible. No apiarist can expect to have his honey sell for the highest market price if it be allowed to stay on the hives for weeks after it has been sealed over, allowing the bees to give the white combs a dirty-yellow color by their constant travel over it and

the brood-combs below. Honey, while on the hive, is evaporated mainly by the heat produced by the bees; and, therefore, if we expect to keep our honey in good condition for market we must keep it as the bees do—in such a condition that it will grow thicker all the while. It should be stored in a room where the mercury can be kept standing at from 80 to 95 F. If stored in this way no honey will drip from any open cells during crating, neither will any of the combs have a watery appearance; but all will be bright, dry, and clean. The supers of sections should be separated so that the warm air can circulate freely all through—under, over, and between each section. Only in this way can the dry warm air treat each section alike. When crating, one should pack sections as nearly alike as possible as to kind and quality of honey as well as to white capping and perfection of combs.

The marketing of honey is a subject that interests every apiarist. As hinted before, it must be attractive. Has it ever occurred to the reader to inquire why the best-selling oranges are rolled up in fluffy paper with lithographs of enchanting faces and bewitching scenes? or why bolts of muslin are labeled with pictures of luscious fruit? No matter how good the quality, our comb honey must please the eye. Hence, instead of loading a bottomless fifteen-pound box into a springless wagon with the bottom covered with straw, as my father did in the early fifties, or putting twenty six-pound boxes into a crate, as did the writer in the early seventies, we now put from twelve to twenty one-pound sections into a no-drip case with a corrugated paper bottom and glass sides. So the attracted customer has dealt out to him a single comb of honey, which, when removed from the section, is far more inviting than all the lithographs the human mind has ever fancied.

All comb honey should be graded and a scale of prices established, based somewhat upon market quotations in the large cities. Remember that transportation and commission will amount to two or three cents per section, besides the risk of breakage in transit. So a sale at home can be made at a cent or two less than market quotations, even though it has to be retailed.

A little practice will make any one efficient along all these lines. If these suggestions are followed, no one can accuse the apiarist of "dumping" honey to break down or ruin the market.

GENERAL CORRESPONDENCE

STIMULATIVE FEEDING IN SPRING: WAX FROM A QUART OF SYRUP

BY R. F. HOLTERMANN

There has been so much said about stimulative feeding that it appears almost presumptuous to attempt to add to that which we now have upon the subject.

Dr. C. C. Miller, in *Stray Straws*, page 925, Dec. 1, says, "The average beginner is deeply impressed with the idea that, whatever his bees are doing in the way of brood-rearing, may be doubled, or at least increased, by stimulative feeding." It took me quite a number of years in keeping bees to realize that stimulative feeding did not always, by any means, tend to the advantageous rearing of brood of a colony; in fact, the beginner would do better to see that the bees have plenty of stores, and then let them do the rest. Dr. Miller goes on to say, "I don't think I have seen the time in 50 years when any amount of stimulative feeding would yield a cell more of brood in my apiary. How could it if the bees already have all the brood they can cover? Of course there are places, as mentioned by P. C. Chadwick, p. 885, where at times there are such breaks in pasturage as to stop the queens' laying, and then stimulative feeding pays big. But in general the notion that the queen should be whipped up in spring to lay more is all wrong, does no good, and may do harm."

The editor, in a footnote, agrees with the above, pointing out the value of feeding under certain conditions for queen-rearing. With the above I can heartily agree, although, even if Dr. Miller has a continuous flow during the spring, surely he must be very exceptionally favored if he has not adverse weather at times when stimulation would be an advantage. It is a safe rule for the beginner not to attempt stimulative feeding. With many, judicious stimulative feeding would be an advantage.

Let me point out an exception. Say the safe rule not to stimulate is when, during spring, there is a continuation of blossoms and the bees work on them daily. The bees bring fresh stores into the hive and the queen is fed liberally, resulting in a liberal production of eggs and brood-rearing. I do not require to look at the combs for the eggs. I know that, under the above conditions, with a normal queen they are being deposited. I have examined colonies, and found that they record their spring activities by the age and amount of brood in the

combs. In fact, it is known to some of us that a colony, if vigorous, is likely to swarm about three weeks after many eggs have been deposited by the queen—in other words, when these young bees are due to emerge from the cells. Take fruit bloom such as apple, cherry, plum, etc. With us, if the weather is fine, much brood will be found in the combs as a result of fine weather, enabling the bees to work on this. But quite often the weather is not fine, and the bees are not stimulated to heavy brooding, and yet the numerical strength of the colony is not one whit less. In such a case I believe stimulative feeding is an advantage. Make the colony in some way handle stores, and the queen will get her share; and she will do her share in producing the brood. I know of no more convenient and better way than to bruise stores in the combs. Start a cell of honey leaking, and the bees will remove the honey and put it about the brood until used for bees or brood. If the stores are not in the hive I would not hesitate to use a feeder with a thin syrup. *Thin* syrup fed in spring saves the bees the trouble and danger of gathering water.

Colonies packed during the spring can rear more brood than those not packed. They are less susceptible to changes of temperature. I know this is true in northern localities, because I have had packed and unpacked colonies side by side in the same apiary.

After a cold night or during decidedly cold days the bees in the unpacked colony are quite inactive on the outside of the cluster, while at the same time those packed were passing at will over the combs in the hive, and therefore better able to supply the requirements of the brood.

When the beginner thinks he is getting to be a very clever beekeeper, and knowing a lot (I think that disease breaks out about the second or third year) he had better be careful lest he do a lot of harm by stimulative feeding; but it seems to me there are times when bees can be stimulated to advantage, and, when possible, this has the effect of increasing the strength of the colony.

Let me say, before I forget it, feeders should not be put on colonies during daylight when the weather is too cold for the bees to fly. Outside stimulative feeding is the most convenient but not the best. First,

there is the danger of the colonies belonging to neighbors getting a part of the supplies; next, the needs of the colonies are not always in proportion to the numerical strength of the colony. Instead of putting open food out in the morning I prefer to put it out as late as possible in the afternoon so long as the bees can get it before it is too cool and dark for them to fly.

SUGAR SYRUP TURNED INTO BEESWAX.

Mr. Editor, will you let me suggest a solution to your statement that your foreman, by feeding one quart of sugar syrup, half sugar and half water, had six frames of foundation half drawn out? My solution is that the side wall of the comb foundation is often thinned and elongated, and therefore a large part of that side wall was made out of the wax side wall, and perhaps a part out of the base of the comb foundation. To test this matter the frame with foundation should be weighed when given to the swarm, and then weighed after the syrup has been fed, and the foundation built or drawn out. Some fifteen years ago I carried on some experiments in connection with my position as lecturer and experimenter in apiculture at the Ontario Agricultural College, and I blackened the wax of which the foundation was made by stirring lampblack with the wax when melted. When the bees were put on this foundation, and built the comb thereon, there was no difficulty in detecting, by the black or shade of black, just how far and to what extent the bees utilized the comb foundation.

The report of these experiments is given in full on pages 358-9 of the May 1st issue for 1896. The following extracts from that report have a bearing on this particular question:

In our experiments, observations were taken along various lines—*first*, as to what extent, if any, the bees thin the base and side wall of the various thicknesses and kinds of comb foundation. Measurements were made, whenever possible, of the weight of foundation compared with the number of square feet, and thickness of the base of foundation. Measurements were taken of the comb at the base, the side wall close to the base, and half an inch up the side wall. The comb was put on ice to harden it for the purpose of more accurate measurement; and three measurements were taken in this case.

Again, to see just how the bees utilized the comb foundation, three tanks of melted wax were prepared. One was colored with a preparation of alkanet, another with a preparation of carbon, and the third was pure beeswax, uncolored. The various stages in the manufacture of comb foundation were carried out, giving comb foundation from each tank ten, twelve, and fifteen feet square to the pound.

These were placed side by side, and drawn out in the upper stories by the bees. It was manifested in various ways that the bees objected to the alkanet, so this kind was discarded. To the foundation, colored black with the preparation of carbon, the bees did not object. The object in placing foundation made of ordinary wax alongside of the colored,

wax was to make measurements of each kind when drawn out by the bees. The measurements of the colored and uncolored, being identical, gave us a basis for the statement that the bees did not object to this preparation; and the method of drawing this out was identical with that of ordinary foundation. The base and lower part of the comb were not, as we might expect, of a black color, and the fresh and added was white. Instead there is a regular graduation from black at the base to white at the top of the cell. The heavier the foundation, the darker the base and adjoining side wall.

FIG. 1. (c)—giving a side view of comb foundation, 15 sq. ft. per pound; and the same after the comb has been completed and capped by the bees. The honey has been extracted, and washed away from the comb, and a section cut down, which, after a thorough drying, has been filled with plaster of Paris.

From the above it would appear reasonable to expect that the bees keep adding scales of newly secreted wax and then pulling the side wall, thus decreasing gradually the percentage of colored wax. We also conclude that the quality of wax used in the foundation has an influence, not only on the base, but, to a certain extent, in almost the entire wall of the cell. The heavier the foundation, the greater the influence on the side wall. Again, notes were taken daily when the bees were beginning to draw out the foundation; and although the heavier foundation was scattered about in the various parts of the upper stories, they gave the preference to the heavier foundation, working on it first. Great caution must, of course, be observed in coming to conclusions. The bees, if the heavier foundation had been taken away, might have been almost as willing to go to work at once upon the lighter grade. At present no way appears open for conducting a satisfactory experiment to prove any thing in this direction. The measurements taken at the base of the wall, and half an inch from the base, all tend to show that the wall is thicker at the base, and tapers, becoming thinner at the mouth. So far as I am aware, no one has ever made such measurements.

The "Vandeusen" is a flat-bottom (unnatural) foundation. The various specimens of this kind which were put into the sections were partially covered to prevent the bees from touching the covered portion. The remainder was left to the bees. In every case the bees changed the base from flat-bottom to natural.

If Mr. Chadwick thinks that all the wall on the foundation, beyond what depth there was on the wall when inserted, is made of beeswax produced by the quart of thin syrup, this is not necessary. I have weighed sheets of foundation when put in the frame or hive (using seven Langstroth sheets to the pound weight). Then after the comb was built out I again weighed the drawn comb and found that the bees just doubled the weight of wax in the frame. If a part of the wax in the comb foundation had not been used for the elongated wall I do not

think there would have been so little difference. Herein is shown an added value in comb foundation. It saves wax secretion and the expenditure of honey, and I almost invariably use full sheets of foundation whether in the brood-chamber or the supers, be they for comb or extracted honey. If a swarm is thrown on the foundation we must remember the bees are in the best shape for secreting wax, and that they will have a lot of wax scales on the abdomen, and, in addition, will be full of honey.

Brantford, Canada.

IOWA ANNUAL CONVENTION HELD AT AGRICULTURAL COLLEGE

BY F. C. SCRANTON

In order to secure the advantages accruing from a meeting at the Iowa State Agricultural College at Ames, which, by the way, is one of the foremost institutions of its kind in the country, attracting students from points as distant as China, it was necessary to set the dates a little earlier than usual. The attendance would have been somewhat larger had the convention been held a month later; but those who gathered there were deeply in earnest. They came for information, for help, to learn how to do their work quicker and better, and every one got what he or she (for there were also a number of ladies in attendance) came for.

The morning session of the first day, Nov. 17, was given over to the usual routine work such as president's address, report of secretary, reports of committees, and appointment of committees. Following this the secretary, Mr. Snyder, read a letter from the Woodbury Beekeepers' Protective Association, urging that legislation be enacted prohibiting one beekeeper establishing an apiary within a certain distance of another beekeeper's apiary, and suggesting that the association enact by-laws making it an offense for one member to establish an apiary within three miles of the apiary of another member without the consent of the member whose apiary is already established. Violation of this would subject the guilty member to a fine of from \$3.00 to \$10.00 for each colony in his apiary.

In the discussion of this paper it was shown that so many conditions, such as locality, season, topography, etc., enter into the subject that it would be impossible to set any exact limits which would be perfectly fair to all. The number of colonies already located would also affect the question of distance apart.

On the afternoon of the 17th, Prof. Bartholomew gave a "short-course" lecture,

using a large model of the bee. His audience was deeply interested throughout the talk. He showed why it is impossible for bees to bite the skin of fruit; compared the œsophagus to the crop in a chicken; showed how the honey-sac is filled with honey in winter, and how it passes through a valve into the stomach as needed; explained how the blood of an insect contains no oxygen, fills all spaces between cells in the body, and how it is supplied at these points with oxygen, and how a constant circulation of this fluid is kept moving through the body.

On the evening of the 17th, C. P. Dadant gave a history of beekeeping. This was followed by an illustrated lecture on nectar secretion and the honey flora of Iowa. It was both interesting and instructive.

At the morning session on the 18th, Dr. Phillips, of Washington, D. C., gave a very instructive talk on temperature and moisture of the hive in winter, both as concerns outdoor and cellar wintered colonies. In conducting his experiments along this line he seems to have established the fact, as stated in the Nov. 15th issue of GLEANINGS, that the bees forming the cluster in winter are not dormant during cold spells, as was formerly accepted, but that they form a sort of ball, the bees in the outer layer of which take a position with their heads pointing toward the center, and remaining very nearly motionless, while those inside this circle fan with their wings, move about, and attend to raising and lowering the temperature. He laid particular stress upon the fact that, when bees are wintered in cellars, proper attention should be given to ventilation and to eliminating moisture from the cellar.

Mr. W. S. Pangburn, of Center Junction, Ia., talked on the subject of cellar wintering. Mr. Pangburn is counted a very suc-

Iowa convention at Ames, November 17-19.

cessful beekeeper; and not only that, but he is also a good farmer.

Prof. Francis Jager, of the University of Minnesota, told what the agricultural colleges can do, and what the Minnesota college is doing, to further the cause of beekeeping.

Most of the afternoon was given to various demonstrations by different beekeepers. Mr. Hall, of Colo., again showed how he fastens foundation in sections, and how he folds his sections, as well as his method of putting full sheets in brood-frames.

Dr. Leonard, of Minneapolis, who is a champion of the split section, showed how to insert foundation in split sections, four at a time, and without several unnecessary handlings of the sections.

Mr. Pangburn demonstrated his method of fastening foundation in sections with but one handling, they being ready for the

super when he finishes fastening the last sheet.

In the evening Dr. Burton N. Gates, of Massachusetts, gave an illustrated lecture. While there was some delay in getting the lantern to operate so the slides would show, there was no lack of interest in his lecture.

The meetings on the 19th were devoted to discussions and to cleaning up the business, such as reports of committees, etc.

Officers elected are as follows:

President, Prof. Bartholomew, of Iowa State College, Ames, Ia. Vice-president, B. T. Bleasdale, Des Moines, Ia. Secretary-treasurer, S. W. Snyder, Center Point, Ia. Directors: W. S. Pangburn, Center Junction, Ia.; J. W. Stine, Stockport, Ia.; A. P. Chamberlin, Des Moines, Ia.

The next annual meeting will be held at Des Moines, at a date to be announced later.

Des Moines, Iowa.

DESCRIPTION OF THE SEVERIN 1914 MELTER

BY F. J. SEVERIN

My latest 1914 design of capping-melter surpasses my 1911 model shown on p. 724, Dec. 1, 1911. It keeps itself clean, and melts the cappings, or whatever there is to be melted, more quickly, and holds only about two gallons of water as it is not so large as the old melter. This 1914 melter requires only one burner on a gasoline-stove. It has only 17 x 13-inch melting surface; but it contains 221 half-inch tubes one inch in length. In other words, it takes nearly 18½

feet of half-inch tubing. The melter top is flanged out wide enough to be 23½ x 19½ inches, and is 7¼ inches deep to the top of the tubes. See Fig. 1. Four frames may be put in when uncapped ready for the extractor. There is a place for two uncapping-knives at the right of the operator, 7½ inches wide by 9 inches deep, taking any size of knife up to 9¾ inches in length.

One inch below the tubes is a spout 6½ inches wide and 3½ long, for the escape of

the honey, wax, and refuse. A waterway of fully half an inch is below the spout. A screw cap lets water out of the melter without tipping it up.

Fig. 1.—Top view of F. J. Severin's new capping-melter, showing the tubes.

The outside is made of heavy Teuton iron resembling galvanized iron, and will resist rust and wear longer than galvanized iron.

The tubes are made of seamless brass tubing, above and below, and are soldered into sheets of heavy tinned copper. The partition catching honey, wax, and slumgum, is also of heavy tinned copper. The tubes are well covered with hot wax and honey as soon as made. These holes are well rimmed out smooth so the cappings and honey will pass through as soon as melted. Having a flat melting surface it melts very rapidly, and will not run down as with a sun-extractor when tilted too much. This melter is supposed to stand level. A flat wooden paddle is used to scrape back and forth the refuse if one is cutting many dark tough combs. I have taken old black combs, brok-

en them loose from the frame, laid them flat in the bottom of the melter, and then uncapped in the clear place, and in a very short time I could take the paddle and pull it through the comb when it would break and crumble up as if the sun had hit it in a good solar extractor. This could not be done with the V-shaped tubes in the old melter, as that melted on the V edges first, and the full amount of heat could not hit the comb as with the 1914 melter.

This melter is by far the best I have ever used, seen, or read about; in fact, it is the result of my long experience in the use of different melters, and in seeing other designs in use.

THE NEW SEPARATOR.

The new separator is also constructed differently from the one of 1911. Fig. 2 shows the separator completely assembled, and Fig. 3 the separate parts excepting one wax-pan.

The separator consists of three parts, all made of Teuton iron—the outside pan, the slumgum-basket, and the wax-pans. The engravings give a good idea of what these parts are and how they are constructed.

The outside pan is 27 x 17 inches. The compartment for the slumgum-basket is 5 inches wide, and as long as the pan is wide. The slumgum-basket is 4 x 16½ inches, having one-inch play to allow it to be slipped away from under the spout of the melter when necessary to empty it, without moving the melter or separator. The contents can be dumped in an old box; and later, after the season, put through a wax-press or dumped immediately into a solar extractor. The basket follows the shape of the outside pan. The whole separator is very easy to dump, and is self-cleaning.

If for any reason one is careless, or wishes to run lots of honey through the separator quickly, it will start little drizzling specks of dirt from the contents of the basket, which will go into the wax-pan. In this case it would be better to put a piece of cheese-cloth inside the basket to catch all such specks of dirt. If left alone, and run as intended, just as every thing comes from the knives, the wax cake will be a bright, clean, yellow wax. The operator can melt comb honey, chunks, or cakes

Fig. 2 —Severin's 1911 separator assembled.

of wax so completely and quickly he will wonder how it is done; and the separator will handle it as fast as it comes.

The wax-pan is 20 x 16 in., and 5 in. deep. There are two pans in this compartment. One rests down in the honey, and the other fits inside of it closely. Both slide under the spout. Consisting of two pans it has an advantage over the other form. By slipping both from under the spout, the cross-bar may be pulled out and the wax-pan inside lifted out. Then one need not get daubed up with honey. If for any reason one should fill the first pan, he can lift it out and shove the other one

under the spout, put the cross-bar back, and keep on melting until that also is full. The outside wax-pan holds 36 pounds, and the other 35. I have never been able to fill either of these pans in a day's run, but have filled it from other wax. I have extracted from 13 to 15 cases of honey a day, getting from 18 to 20 pounds of wax.

This separator is probably too large for the average beeman, but can be made any size desired. The reason I made this size was because the wax cake fitted a gunny sack much nicer, and I did not have to stop my work when the separator was full, as

was the case with the 1911 separator. The new one has a great deal more slope than the one of 1911, and cuts all the surplus honey out, as the wax-pan closely follows the slope of the outside pan. There is a screw-cap outlet near the bottom to draw

Fig. 3.—The new separator, showing the parts.

off the honey each morning down to the $\frac{3}{8}$ -inch partition. Always, when through with a day's work, the slungum-basket should be lifted out, a sack thrown over the separator to let all cool together. The next morning the large cake of wax is ready to take off. Where the slungum-basket was will be a $\frac{3}{4}$ -inch piece of solid wax, which must be removed to make room for the basket again.

A $1\frac{1}{2}$ -inch pipe carries the honey from the separator to my extractor-pipe. From there a $2\frac{1}{2}$ -inch pipe carries it into the tank.

Imperial, Cal.

REPORT ON APIARY INSPECTION AND DEMONSTRATION IN ONTARIO, 1914

BY MORLEY PETTIT
Provincial Apiarist

It has not been found necessary to make much change in the management of the inspection of apiaries from the methods reported at previous conventions. In accordance with a resolution passed at the last annual convention, more local inspectors were appointed than ever before; but with this exception the work has been carried on much as usual.

The inspectors' conference was held at the beekeeping short course in January at the Ontario Agricultural College. A letter, warning against danger of spreading disease by allowing bees to rob, was sent to the general list of beekeepers early in the spring, and the self-inspection report-forms went to the disease list of beekeepers in

May. These were given a hearty response by the recipients.

Twenty-one apiary inspectors were employed. Nine of these were strictly local inspectors; that is, they are practical beekeepers appointed to inspect bees in their own and adjoining counties. Eight have taken some training at the Ontario Agricultural College, and have returned to their homes to keep bees. They also acted as local inspectors. The four remaining men were sent out directly from the Ontario Agricultural College, after having received a special course of training in apiary inspection and in conducting apiary demonstrations.

One thousand three hundred and sixteen

visits were made to apiaries by inspectors during the season of 1914; and while in the European-foul-brood districts half of the apiaries visited were found diseased, only 31 per cent of the apiaries visited in the American-foul-brood district were found to be in this condition. In other words, whereas the inspectors went only to apiaries where disease had been reported or was strongly suspected, seven out of ten such apiaries in the American-foul-brood district were found to be free of disease. This shows that the educational campaign which we have been conducting for several years is bearing good fruit.

While it is exceedingly regrettable, it is not surprising that European foul brood is still spreading rapidly. Some new counties have been taken into the diseased area this year. It is only a matter of time when the whole province will be covered. Nothing but careful requeening with vigorous stock and advanced methods of management will save any apiary in Ontario from ultimate destruction. By our publications, demonstrations, and inspectors, practically every beekeeper of Ontario has been repeatedly warned, yet comparatively few have taken heed or will heed until the enemy is upon them, and they have suffered heavy loss. In the infected area the business has been reduced to the very few who have taken advice and are building up their apiaries again to a paying basis. These few are proving the truth of what has been said, and their evidence is of great value in the educational campaign still being waged in advance of the disease.

No doubt one reason for the indifference to warnings in the European-foul-brood counties is the fact that previously no bee disease had been known there. It is only this year that the American and European foul-brood territory began to overlap in Victoria County. From now on we can expect an increasing number of cases of the two diseases in one and the same colony. This will, no doubt, make it necessary to treat all such colonies by requeening for European foul brood, and by shaking for the American variety of disease.

Fifty-five apiary demonstrations were held in all parts of Ontario, with a total attendance of 1861 persons. In 1912 the average attendance was 25; in 1913 it was 32, and this year 34, showing an increased interest from year to year.

This report would not be complete without mention being made of the public spiritedness and the hospitality of several who have given their assistance. Fifty-five beekeepers have at considerable inconvenience allowed their apiaries to be used for demonstrations. In many cases their wives and other ladies of the neighborhood have provided refreshments for the demonstrators and for the beekeepers in attendance. Hundreds of other beekeepers have given a hearty welcome and cordial hospitality to the inspectors on their rounds. All this is very much appreciated, both by the inspectors and by the department, and goes a long way toward smoothing the path of the public servant, which is not always lined with roses.

Guelph, Ontario.

POWER EXTRACTORS DRIVEN BY FRICTION INSTEAD OF BY BEVEL GEARING

BY H. H. ROOT

Ever since beekeepers began to use power honey-extractors there have been complaints regarding several features in connection with the construction of the driving mechanism, and a number of beekeepers have substituted other devices such as clutch pulleys, loose pulleys with a belt-shifter, etc., the idea being to secure a more flexible device for starting the extractor, and one that could be operated with less effort, even when the hands are slippery with honey. Again, a number have written regarding the desirability of some scheme which would allow the pump to run all of the time instead of only while the reel is turning, so that it may have a longer time to do its work and thus be allowed to run at a some-

what slower speed. In employing a friction drive instead of the usual bevel-gear drive we feel that we have secured several important results—first, *doing away with the idler or belt-tightener*. This device has frequently been a cause of complaint; for, besides being rather hard to operate, it is difficult to get the proper degree of tension on the belt to start the reel as gently and yet as quickly as required. For instance, one notch may leave the belt too loose, while the next makes it too tight. Furthermore, a belt will not last as long when its "back is broken" by being bent both ways in passing over an idler-pulley.

Second, *allowing the pump to run all the time*.

Fig. 1.—The cam-lever in a horizontal position, the extractor reel at rest.

With the friction drive the cross-shaft of the extractor runs all of the time as does also the pump. This means that the pump does not have to run quite as fast any of the time and consequently the load on the engine is reduced, and danger of slipping of the pump-belt is prevented.

Third, *allowing a variable ratio instead of a fixed ratio, as in case of beveled gears.* By this we mean that, in case the engine-pulley is not just the right size to turn the extractor at the proper speed, or if the speed of the engine cannot be controlled to the right point, the ratio between the driving-disc on the cross-shaft and the driven paper pulley on the vertical reel-shaft may be changed. Possibly there are some who do not understand the principle of what is known as the friction drive. It may be well to explain, therefore, that in this particular form of friction drive a metal disc with a perfectly smooth flat surface runs all the time, being located on the cross-shaft of the extractor. When it is desired to start the extractor-reel this revolving disc is brought into engagement with a paper-rimmed pulley on the reel shaft; and rolling against it, as it does, the reel speeds up, the rapidity with which it reaches its maximum speed depending entirely upon the amount of pressure brought to bear by the disc against the paper pulley. Now, if the

ratio of the drive is not quite correct—for instance, if the reel turns too fast, so that there is danger of breaking combs—the paper pulley may be raised, say, $\frac{1}{4}$ inch on the reel-shaft, so that it is nearer the center of the driving-disc, and then the disc will not drive it quite so fast. On the other hand, if the reel does not turn fast enough the paper pulley may be lowered so that it runs nearer the outside of the disc, making a higher speed.

Fourth, *doing away with noise and danger of a breakdown.* Beveled gears, unless submerged in grease, are noisy, and wasteful of power. There is also the possibility of breaking a tooth, due to the power being applied too suddenly, causing an expensive delay.

To show that the friction drive is ample as a means for transmitting power, one has only to point to well-known makes of automobiles such as the Cartecar, Lambert, Metz, etc., in all of which the friction drive is successfully used. The illustration on page 22 shows the friction drive as used in the Cartecar. The success of this particular make of machine in climbing grades even as steep as 50 per cent is too well known to need further comment here. From over a year's experience with the friction drive as applied to honey-extractors, we believe that the paper rim of the driven

Fig. 2.—The cam-lever in the vertical position. The disk is thus crowded over against the paper wheel on the vertical shaft so that the reel turns.

pulley will last longer than a set of beveled gears.

TO OPERATE THE EXTRACTOR.

Fig. 1 shows the driving mechanism with the cam-lever turned down in a horizontal position. Fig. 2 shows this lever pushed up to a vertical position, in which case the cross-shaft and disc are crowded to the left so that the disc is in contact with the paper pulley on the reel-shaft, thus causing the reel to turn. There is only one adjustment necessary, and that is the position of the collar on the horizontal cross-shaft of the extractor, which receives the thrust from the spring when the cam-lever is in a vertical position. Fig. 2 shows this collar and the set-screw that must be loosened when the position of the collar is changed. If

position, the tension is released automatically by the shape of the cam to relieve unnecessary strain on the bearings. A very slight pressure on the part of the disc against the paper wheel is sufficient to keep the reel moving at high speed, when it is once under motion; therefore the adjustable collar should not be located any closer to the cam lever than is necessary to keep

Fig. 3.—Ideal arrangement of extractor, pump, engine, tanks, etc.

this collar is too close to the cam-lever the tension on the spring when the lever is in the driving position will be too great, causing an unnecessary strain on the bearing. On the contrary, if the collar is too far away from the lever there will not be enough tension to drive the reel.

It will be noted that the shape of the cam-lever is such that the greatest tension on the spring (and consequently the greatest thrust) occurs when the cam-lever has been moved up about half way to the vertical position. A little more tension is needed at the start to get the reel speeded up; but when the proper speed has been reached, and the lever moved on over into the vertical

the reel turning at full speed when the lever is in a vertical position. When the adjustment is correct the lever will turn up or down easily, requiring very little effort.

LOCATING THE MACHINERY AND TANK.

Fig. 3 shows the arrangement of the extractor, pump, engine, tank, etc., that we recommend. The outside door to the extractor room should be on the side nearest the capping-melter or uncapping-tank, so that the full supers will not have to be carried about the room any more than is absolutely necessary. All new belts will stretch slightly at first, after they have been run a short time. It is well not to locate the engine, pump, etc., too permanently at

Fig. 4. — A closer view of the pump, showing the connections.

the start, for they will surely have to be moved slightly one way or the other to make up for the stretch of the belt. After the belts have once been "broken in," any further stretch is so slight as to be almost imperceptible.

The pump-base is secured to the floor by means of large screws or a small coach or lag screw. These should be started at the end of the slots furthest from the extractor, so that, as the belt stretches, the pump may be moved back away from the extractor slightly by loosening the screw. Fig. 4 shows a closer view of the pump and its connections to the extractor, through an opening in the gate. This connection does not inter-

fere seriously with the opening of the gate if desired. In this position the discharge pipe that takes the honey from the pump to the tank is out of the way and does not interfere in any way with the operation of the extractor.

The engine does not require a stone foundation, an ordinary wooden floor being solid enough unless the timbers are in very bad condition. We usually secure the engine to the floor by boring a hole through each end of each skid and inserting long lag screws into the floor through these holes. A somewhat easier plan, and one that permits some change in location on the floor, is to select two pieces of 2 x 4 material, each a trifle longer than the width of the engine-bed. Cut a notch in each end so that the piece will fit down between the handles at the ends of the skids. Bore a hole in the center, and then by inserting a long lag screw into the floor the

ends will be clamped down. Later on, if necessary, the two screws may be loosened

Fig. 5. — An extractor located on the floor is much more convenient when it comes to putting in or taking out combs.

slightly and the engine pushed back away from the extractor, to make up for the stretch of the belt.

Fig. 3 also shows a good arrangement for a strainer. This is a combination of strainer and settling-tank which works admirably. A small barrel with both heads knocked out is as good as any thing for the inner can. Heavy cheese-cloth is firmly tied over the lower end, and the barrel supported as in the illustration, so that the cheese-cloth is three or four inches from the bottom of the main tank. The honey is pumped into the inner tank (or barrel); and as soon as it reaches a level above the cheese-cloth the bits of cappings and all foreign matter will float to the surface away from the cloth so that the latter may accomplish its purpose of straining the very fine particles without becoming clogged. For best results the

honey should be allowed to fill the large tank nearly full before any is drawn off, and it should be drawn off no faster than

Friction drive of Cartecar

any is pumped in, in order that the level may be kept well away from the cheese-cloth.

POLECATS IN THE BEEYARD

BY H. R. BOARDMAN

I have been aware for some time that skunks seemed to be attracted to my beeyard. I have found them occasionally scratching at the entrance, but it did not

dawn upon me that they were robbing the hives of the live bees until quite recently.

During the moonlight nights of October and November I caught them on their job.

Flashlight of polekitty robbing H. R. Boardman's hives.

By scratching the hives the bees would be disturbed and run out at the entrance to drive away the intruders. These expert night robbers, without gloves or veil to protect them, would gobble the bees up, apparently fearless of stings, "and working with a zeal worthy a nobler cause"

I think the loss of bees quite serious. I have 115 colonies in the yard, and most of them, I think, have been worked by the skunks. What the skunks are doing to my bees they are doing to the bumblebees.

Look carefully, Mr. Farmer, and you will find many of the holes in the meadow and pasture you thought were dug for grubs were dug for the nests of bumble-bees. And

don't forget the nests of Bob White, because the echo of his sweet song is far more pleasant than the "aroma" of the skunk.

Collins, Ohio.

Caught with the goods on. Another remarkable flashlight photograph.

BEEKEEPING IN SOUTH AUSTRALIA

BY A. P. HABERECHT

In my locality the season ending last May was one of the best I ever experienced. My average for 66 colonies was 125 lbs. extracted honey, and all supers full of stores; about 2500 lbs. of surplus, which, if I could have extracted, would have brought the average up to 161 lbs. per colony; but on account of the coolness of the weather and the thickness of honey I was unable to do so. The honey-flow lasted up to the end of April.

My honey was so thick that I could do nothing with it below 90 degrees, and only at 100 would it extract freely. My reason for this was continual high winds during the main honey-flow, the bees working only mornings and evenings, and fanning all the rest of the time. My bees worked very evenly this season, 50 per cent best, 40 per cent well, and 10 per cent that brought about 60 lbs. of surplus—no difference as to color or breeding. The best Italians seem to fly earlier and faster, but do not seem to put more into the comb-bucket. The only conclusion I can come to is that they must consume more stores.

The red gum (*Euc. rostrata*) turned out a complete failure with me last season; but it looks very promising for next season.

The yellow box (*Euc. melliodora*) bloomed from the beginning of September to the end of February, which happens only once in a lifetime. It usually blooms from the end of July to about the end of October; but this season it has no buds, so there will be no bloom on yellow box next season at all, perhaps only an odd tree. The gray box (*Euc. hemiphylora*) bloomed very patchy, but a good sample (our fall honey).

I sold 75 per cent of my honey to the consumer at 8 cents per lb., and 25 per cent to dealers at 7 cents, and my beeswax was sold at the market at 28½ cents, the highest price I ever had for beeswax.

I would strongly advise all apiarists to do their best to sell as much as possible to the consumer, get their honey up in suitable lots, and make a house-to-house canvass; but the honey must be put up attractively. There is a great future for the apiarist; but he must keep on teaching the people to eat honey. You will find that, the more people eat honey, the better they will like it, and the more they will eat. I cannot say that I know of one person who said, "I used to eat honey, but now I do not care for it."

My experience is, if a family takes 30 lbs. of honey this season I am sure they will

take 60 next season. The trouble is to induce them to buy the first lot, however small it may be; but if the advertising and the canvassing are left to the dealer we are lost.

My idea is to sell all the best honey first, tell the customer that all the best honey is sold out, get him to taste the other, and he will take it and be satisfied, even if it is inferior. But he will get in earlier next season and buy more than ever. I sold all my best first, and the fall honey went just as quickly afterward.

Our Royal Agriculture Show took place at Sydney at Easter time. The weather was perfect, the attendance a record (95,000 people on Good Friday, the main day); but the bees and honey exhibits were very few and poor. I went 360 miles to see it, and I was very much disappointed. I exhibited

only in the district exhibit. There were practically only two exhibitors and one experimental farm instead of about twenty or thirty contributors; but our brother apiarists do not seem to care or bother so long as they get their honey away at any price. Our district honey exhibit got 18 points out of a possible 20, so we did fairly well.

Perhaps it would be interesting to some of your readers to know that my grandfather brought one colony of bees from Germany with him in 1848. Bees were then unknown, so far as I know, in South Australia. They were twenty weeks on the water, and came out in good condition. The first honey was sold at 25 cents a pound, and the first swarm sold brought 5 pounds. Those bees were pure blacks.

Henty, N. S. W., Australia.

THE HODGSON BEE-ESCAPE BOARDS

Auto Truck in the Apiary, and New Twelve-frame Friction-drive Extractor

BY R. F. HOLTERMANN

There has already been some notice of the Hodgson bee-escape board, which has a wooden frame with the main part of it wire cloth. This is the invention of Mr. Arthur F. Hodgson, Jarvis, Ontario.

The ordinary bee-escape board has been objectionable to me because, owing to lack of ventilation when put under the supers, only one super can be put above it at a time. When we go into an apiary we want to make a complete job of extracting in one day. Next, the bees being off the combs for some time before extracting, and the heat of the bees being shut off by the solid bee-escape board, the honey cools, and therefore it is more difficult to extract. Of course this latter difficulty has been overcome in part by the use of power extracting-outfits.

Last season I saw the way in which these escape-boards worked at the apiary of my son Ivar, and it was practically demonstrated to me that they are the proper thing for a well-equipped apiary. I have now 250 of these escape-boards, made for me by Mr. Hodgson. This is enough for the apiary we may be extracting in, and for the apiary in which we may want to extract the following day. I use a double-outlet Porter bee-escape in each board; and because of these two outlets instead of one I think the bees leave the supers in about half the time.

RESULTS.

The boards have proved themselves a very great success. We have put them on at almost every hour of the day. Our prac-

tice for quick work is for one to lift the super, another to smoke, and a third to slip the escape-board on the hive. This is particularly desirable when there are two supers on a hive; but one can do the work by removing the super and setting it down until the escape-board has been placed on the hive. This year, however, we did not have many second supers, and in no case was the second super full. The escape-boards are best put on quickly after the super is raised and the super returned as quickly. This prevents, to a very great extent, the bees from getting between the surfaces of contact, and thus, of course, killing bees or taking a long time to brush them away.

As to the time it takes for the bees to leave the supers we found it quite feasible to remove the supers five or six hours after the escape-boards were put under them, thus enabling us to put some of the escape-boards on in the morning, and extracting from them the same day.

I found that the bees begin to roar very soon after they are separated from the brood and queen below (their action is the same as if they had been smoked too much). Mr. James Armstrong, Cheapside, Ontario, a well-known beekeeper, told me that he and his son go to the hives soon after putting on escape-boards; and unless the bees are roaring, which can be heard from the outside, they know there is something wrong, and they investigate to find out what it is. Per-

Holtermann's power truck with a load of empty 12-frame supers.

haps some beekeepers do not know that, if the queen and brood are there, the bees will remain contentedly in the super.

We found a few young bees in some supers; and occasionally, after being on only five hours, some more bees; but there were not enough left to make the removal of the supers of honey inadvisable if they were needed that soon.

I remember coming to a super with a lot of bees on the combs, and saying to one of the students, "We will investigate the cause. Perhaps the bee-escape is clogged."

We found the escape raised at one side so the bees could pass back into the super, so that there was really no bee-escape board on that hive.

The honey extracts readily with the twelve frame friction-drive extractor. We have now used these boards in five apiaries, and there will be no more shaking and brushing of bees from the combs of honey in the supers.

In the years gone by I myself have nearly always had the work of removing the honey from the hives and freeing them from the bees by sharp shakes; and I have found this no light work when followed up day after

day about as fast as a rather active man can move. It jars continually the whole system.

Another advantage in the bee-escape board is that it prevents the demoralization of the apiary at a time when it tends to robbing and the making of cross bees. However, let me sound a note of warning. There must be no chance for robber bees to get into the super from which the bees have been cleared.

THE AUTO TRUCK FOR TRANSPORTATION.

Accompanying this article is an illustration of the auto truck

I have purchased to use in connection with apiarian work. As seen in the illustration it is loaded with forty supers (twelve-frame), containing combs which have been extracted, and which are about to be returned to the apiary from which they have been taken.

I find this truck a very great advantage. It has a capacity of 1500 lbs. weight. There are times when a truck of greater capacity would be very convenient; but the desirability of this increased capacity is confined to so short a time that it would, in my estimation, be more than counterbalanced by

R. F. Holtermann with his son Glenn and five students, who were with him during the season of 1914

the extra expense of running the heavy truck.

This truck can be run into a beeyard, and loaded or unloaded without any fear about stinging horses; and there are not many days in summer when rain prevents its use.

We used the Hodgson wire-cloth bee-escape boards this season, as before stated, thus doing away with all brushing and shaking of bees from the combs of honey, and extracted the honey from seven apiaries at two points. If the honey crop had been any thing like a normal one, of, say, 50 lbs. to the colony, it would likely have paid us better to move the honey-extractor to the honey instead of moving the honey to the extractor.

Another use for the truck is to transport the workers from home to outyards. From the accompanying illustration it will be seen

we had quite a number of learners and workers—one each from New York, Pennsylvania, Jamaica, Cuba, Wales, and three from Ontario, Canada. The one from Wales and a lady from Ontario do not appear in the engraving.

THE FRICTION-DRIVE EXTRACTOR.

While on the subject let me say we substituted for the bevel gears on the twelve-frame extractor a friction drive, and also ordered another with this equipment. We found a wonderful improvement in the running of the extractor. A great advantage is that the honey-pump runs all the time, keeping the bottom of the extractor always in view. The extractor, too, can be operated with less trouble. Every power extractor should be operated by means of friction.

Brantford, Canada.

PURGATIVE DRUGS FOR BEE PARALYSIS

BY M. Y. CALCUTT

I have noticed in GLEANINGS for several years past more or less discussion regarding that peculiar disease known as bee paralysis. It is to me the most peculiar of all bee diseases I am acquainted with. I have had my experience with American foul brood, but am no longer alarmed over its visit to my apiary as I have learned how to handle it successfully. Bee paralysis I have also been visited with, and have successfully coped with it, so I do not dread its call, although I am not hankering after future visits. But I am not sorry for the visit I have already had, because I am somewhat like that grand old beekeeper, Dr. C. C. Miller. I have had more than my share of enjoyment attending to the bees, overcoming their affliction, and keeping them out of their difficulty; so, as A. I. Root says, it is a great satisfaction to feel that you are able to conquer the difficulties that are presented. It has always been my hobby to tackle something that people say cannot be done. Our pleasure lies in demonstrating that it can be done if we only have the patience to go ahead and do it.

Now, Mr. Editor, let us take a good look at this strange disease and see what is the matter. Some say it is due to the honey they gather, and some say it occurs only in hot weather. Others tell us it is due to the queen, and that requeening is what we must do to get rid of it. Now, I have found that they are all wrong. It is not due to the honey they gather at all, as I have had bees afflicted when they did not gather any honey,

nor had they anything but white-sugar syrup. Then, again, I have cured them without any change in the queen. Now, N. L. Stapleton, of Colquitt, Ga., page 723, Oct. 15, 1913, will say, "Yes, but you had a suspension of brood-rearing." No, not at all. The queen kept right on laying, and the cure was effected just the same.

What is the cause of it? The bees become pollen-clogged; and unless they are relieved they will die. How can they be relieved? If they are not storing honey in the supers, just give them a cascade dissolved in a little water and mix the same in a jelly-glass of sugar syrup, 1 to 1. It is well to repeat this for three or four days according to the size of the colony, then the trick is done.

Now let me add that I fully agree with Mr. Stapleton in all he says, with the exceptions as here stated. A discontinuance of brood-rearing will also effect the cure. If they are storing honey in the super this is the proper method to cure the disease.

Some writer has said we cannot cure it and get a surplus the same year. Now, this is wrong again, for I am doing it right now. To explain, last spring I had a colony badly affected. They were pulling them out by the hundreds, and they were hopping in all directions. As they crawled around they resembled laying queens. One would think they would burst, so distended were their abdomens. This colony was on a Hand switch bottom-board, so I put the queen into the empty hive with a frame of brood,

and threw the lever, switching all field bees to their new hive, giving them the cascade as mentioned. The other half raised a queen of their own. Here Mr. Stapleton is corroborated in his experience—brood suspension. The other half, with queen and field bees only, cured by the cascade. When these two halves had built up, which they

did by feeding syrup, I united them again and put on supers, two queens working here; and now they are hard at it, storing in the supers. So we have nothing to dread here. Just pass this along to our bee-friends, and they can try it out for themselves. It is worth the trying.

Seattle, Wash.

THE ALEXANDER METHOD OF INCREASE

BY J. G. BROWN

[The writer of the following article was a beekeeper in Pennsylvania; and after that he removed to Colorado, where he spent eight years in the business. He is now with the A. I. Root Co. as assistant apiarist in the A. I. Root Co.'s apiaries.—Ed.]

I read with a great deal of interest Dr. Miller's reply to A. Swahn, Dec. 15, page 979. I wondered at the time if the doctor had been educated for a lawyer, or how he managed to get so much sarcasm into two inoffensive-looking little questions as the following: "What successful man doubles his white-clover crop by dividing his colonies before the white-clover harvest?" "What successful man (or unsuccessful) increases his white-clover crop *each* year by dividing his colonies before the white-clover harvest?"

In reply to the above I'd like to ask Dr. Miller if he ever tried the Alexander method of increase, using it just as Mr. Alexander did, and leaving out nothing "because he knew it wouldn't work."

Mr. Alexander does not say that he gets "twice as much" honey when he divides as when he doesn't, but "nearly twice as much." Dr. Miller makes no room whatever for poetic license. Mr. Alexander further says that he has two good strong colonies in the place of one to commence work on the clover harvest. But he does not say they are of equal strength, nor does he say they are "as strong as" the one not divided. The fact that he says they gather "nearly twice as much" implies that he meant they were not quite equal to one undivided at the *beginning* of the season. Mr. Alexander doesn't even say he gets *any* more white-clover honey, but that he has two good strong colonies ready to go to work in place of one. Mr. Alexander gives two illustrations, and in each case he recites what was accomplished at the *end* of the season.

As a further proof that Mr. Alexander did not mean that the white-clover crop would be doubled, he speaks of the new colony on the old stand being "in fine shape for a super of sections," but he does not say the other colony is in shape for a super of sections.

Mr. Alexander began by using what he

called fairly strong colonies about April 15, with a queen not over ten months old, and these he fed **every day** they couldn't get nectar up to and after dividing them. One queen was laying her best up to June 1, and after that he had two queens laying. The first colony contained all the field bees up to May 26, and had a hive nearly full of brood. The second colony had the young and hatching bees, and a young laying queen after about June 1. The flow began about June 15, so the second colony had bees old enough to go to work on clover.

From this time on until the close of buckwheat Mr. Alexander had two colonies gathering honey in place of one. It must be remembered that Mr. Alexander ran for extracted honey, and I have no doubt he was well provided with good brood-combs so that each colony had a hive full of combs at the outset.

Dr. Miller in calling for examples, like the angel at Sodom and Gomorrah, is willing to be "Jewed down" a little. He asked for two living examples of successful men who doubled their white-clover honey by dividing their bees, or two successful (or unsuccessful) men who increased their white-clover crop by dividing their bees before the harvest. Some of us might get into the discussion by way of the parenthesis. If Dr. Miller will concede that white clover isn't the only flow there is, perhaps some of the beekeepers of the West who really keep bees, and, in return, are kept by them, may be able to break into the discussion.

The Alexander method of increase, on the whole, is all right and sound doctrine. That, like all other methods, will have to be adjusted to fit the locality where it is to be used. This is not merely belief, but to me personal knowledge. I used it in Colorado, but fed outside instead of using individual feeders. The result was, colonies were boiling over with bees much earlier than the apiaries where not so stimulated. Both

parts of the colonies divided on this method were, in a few cases, ready for the first alfalfa flow, beginning about June 18, while others did not go into the supers (comb honey) till later.

But I should like to give Dr. Miller the names of some of the beemen of Colorado who use this method to a greater or less extent in making increase, unless he insists on the white-clover test, and that would, of course, shut the Western beekeepers out.

Mr. J. C. Mathews, of Montrose, Colo., who owns and operates 1000 colonies, who is successful in the commercial end of beekeeping as well as the theoretical, uses the Alexander plan very largely. Mr. Mathews says he regards it as the best-known plan of increase.

Mr. E. D. Nichols, a beeman of many years' experience, of Montrose, Colo., uses this method of increase, and says the two resultant colonies will produce much more honey than the one undivided. Mr. Nichols keeps a close record, and can tell each colony that gave him surplus and how much. Mr. Nichols uses a comb-honey super on the colony on the old stand, and an extracting-body on the other for the first super.

Mr. J. J. Corbut has had a large experience in building up colonies, and he uses the Alexander plan largely. Mr. Corbut is a very observing man, and pays plenty of attention to details. When he adopts a method you may be sure there is a good reason for it.

William Corbut and Marion W. Harvey use the Alexander plan with the Doolittle plan and the Dr. Miller plan, and endorse all of them. This, of course, depends on what they want and the method they use.

Mr. Roscoe Miller, president of the Montrose County Beekeepers' Association, and a man owning nearly 1000 colonies, uses this method of increase. Mr. Miller does not believe in sacrificing honey for increase,

and yet he believes in the Alexander plan. Don't get the idea that those beekeepers never use any other method. They are keen, wide-awake, practical men, always ready to take up any thing good or to try it once; and these men consider the Alexander plan, adjusted slightly to suit their conditions, a good practical method, and one with which any one who is willing to take pains can be successful.

Mr. Geo. H. Rea, head of the apiary department for the A. I. Root Co., used the method in Pennsylvania, and knows it will work when followed in detail.

If Mr. Swahn will provide himself with a copy of "Alexander's Writings on Practical Bee Culture," and for good measure throw in a copy of "Management of Outapiaries," by G. M. Doolittle, and read them during the present winter, he will be able to increase materially his honey crop any season by following these two able writers. Even if he have but one colony I think he will be able, with his increased knowledge, to pay for these two publications in increased amount of honey the first year.

I think, Mr. Editor, you should not omit any detail of this method from your next edition. Remember your book and your magazine are read by professionals as well as novices, and the former class, at least, prefer to do their own eliminating when necessary. Don't conclude that this method is wrong without a proper hearing. Dr. Miller has given his opinion, but does not say it is based on any fact or experiment which has proven the contrary "in his locality."

Your own apiarist is of the opinion, backed by numerous tests that he can demonstrate to your entire satisfaction, that he can increase your *white-clover* crop by following the Alexander plan in detail and omitting nothing.

GUARDING AGAINST BEESTINGS

BY RUTH C. GIFFORD

It is a peculiar sensation to be so badly stung by bees that every one, yourself included, thinks you are going to die. Few beekeepers in this community who have that sort of experience ever handle bees again. I happened to be one of the people who kept on; but the time I had could not be described by the word "pleasant." Of course the only thing for me to do was to use a suit that was practically sting-proof. As I could not find either a description or

an advertisement of that sort of suit I had to experiment. Every time the experiment did not work I got stung literally as well as figuratively. The amount of ingenuity shown by those bees in finding places through which to sting was simply wonderful. However, I think my troubles are over so far as a bee-suit is concerned, because I have not had to modify this one during the past two seasons.

I am now going to describe my suit. If

any woman makes one like it, and follows these directions carefully, I don't see how she could be bothered by stings. The suit consists of gloves, bloomers, and a blouse and wire bonnet, which are sewed securely together. The material for bloomers and blouse is unbleached muslin. The bloomers are made very long. The top is held securely around the waist by a long drawing-string. They are also fastened securely around the ankles, over high shoes, with two more drawing-strings. If they are not made long they will pull up, and the bees will sting around the shoetops.

The gloves are men's heavy goat-skin work-gloves. They have a disagreeable odor; but a thorough smoking with a bee-smoker will help that. The bees don't bother by stinging through these, even when they are wet. I always sew a three or four inch strip of muslin to the tops of the gloves; then they won't pull out from under the sleeves of the blouse.

The blouse has the sleeves made long with elastic in them around the wrists. The body part is very wide. To be on the safe side it should be $2\frac{1}{2}$ times as wide as the coat. Another drawing-string fastens it around the waist. The neck is cut out until it fits around the bee-bonnet comfortably.

The bonnet is the most important part of the costume. Take a piece of ordinary wire mosquito-netting, 10×34 ; wrap one end over the other and sew securely. Over one end of this wire cylinder sew a round piece of muslin and bind the edges of the other

end with two thicknesses of muslin. To this sew a five-inch muslin curtain. Then, if it gives you the headache to look through the netting, cut out a rectangular piece of wire. Don't make this any larger than necessary. Bind the edges of the opening with a narrow strip of black material. Measure off a piece of fine wire, such as you use in wiring brood-frames, long enough to go twice across the long way of the rectangle, and another piece long enough to go across the narrow way five times. Put these in so the spaces between them are about equal, and twist each wire around the other. That prevents them from pulling in any direction. To do this, fasten the ends of the wire which run the long way last. These two ends will, of course, come on the same side. If you want to take the shine off the wire, soak it in lemon-juice for a few minutes or in hydrochloric acid about one minute before you use it. After the wire is in, sew a piece of silk tulle over the space, and leave it loose. Then put on the bonnet and blouse, and have some one sew them together.

This suit sounds complex; but if you happen to be one whom the bees take a special delight in stinging you will find it very convenient. The bloomers and blouse can be made "any old way," just so they're big, and sewed tightly. This suit will last several years, and only a few minutes are required to rip out the bonnet when the suit needs washing.

Northeast, Md.

BEESWAX IN EGYPTIAN TOMBS

BY GEORGE BUTLER

During the visit to Queensland of the members of the British Association for the Advancement of Science some very interesting particulars were elicited from Professor G. Elliott Smith with reference to his researches in Egyptian tombs. He is a scientist of considerable note, and any information coming from such a source would not be questioned by any living man. He is a great authority on the mummies of Egypt, and at one time held a prominent position in that country under the government. The subjoined information was the outcome of a letter received by the writer from a fellow-beekeeper in Queensland, who stated that the professor, in conversation with a friend of his, had mentioned that, during excavations in Egypt, he had discovered a jar of honey, the odor from which was sufficiently strong to attract the attention of bees which were flying near. To obtain a

verification of these facts the writer communicated with Professor Smith, who supplied some interesting facts on the subject.

Mr. Smith said that, several years ago, in the course of excavations in the valley of the tombs of the kings at Thebes, the tomb of the parents of Queen Tiy, wife of the Pharaoh Amenhotep III., was discovered, and among the rich furniture found in the tomb was a large alabaster jar containing a thick honey-like liquid which Mr. Theodore Davis, who supplied the funds for the excavation, mistook for honey. The professor ridiculed the supposition that honey would remain in a liquid state for thirty centuries in a dry climate like that of Egypt. When investigating the contents of the tomb he took a sample of the honey-like substance, which smelled like castor-oil, and asked the Government Analyst in Egypt

(Mr. Lucas) to examine it. The surmise he had entertained was found to be correct. It was castor oil. This statement was somewhat disappointing.

It appears the Egyptian women, both in ancient times and at the present day, use castor oil for dressing their hair and anointing their skin to keep it soft. The profes-

sor, however, found considerable quantities of beeswax in ancient Egyptian tombs. It was used to make shields to protect the eyes, ears, nose, and mouth of mummies, and to preserve their features from injury. The ancient classical writers say honey was also used for mummifying.

Red Hill, Brisbane, Queensland.

MINNESOTA CONVENTION REPORT

BY HARRY G. BRANT

The Minnesota Beekeepers' Association held its annual meeting in the Engineering Building of the State Farm School, Dec. 2 and 3, in connection with the Minnesota State Horticultural Association. About one hundred beekeepers were present, quite a few ladies among them. The excellent program was followed out, and a profitable and enjoyable time was had by all. Here is the program:

WEDNESDAY FORENOON.

- 9:00. Social hour.
- 10:00. Meeting called to order. Reading minutes of last meeting. Report of Secretary and Treasurer. Correcting wording of Constitution.
- 11:00. Bee-inspector's Report, J. Alf. Holmberg. Address, "Bee Disease," C. D. Siehl. President's address.

WEDNESDAY AFTERNOON.

- 2:00. "Progress in the beekeeping industry in Minnesota the past year," Francis Jager, Prof. of Apiculture, Agricultural College. A. F. Woods, Dean of Agricultural Department, University of Minnesota. The Law of Mendel applied to the breeding of bees, C. E. Bartholomew, Prof. Apiculture, Iowa College.
- 3:30. Symposium on comb-honey production: "Fastening foundation in sections" (a demonstration), L. M. Bussey. "Fastening Foundation in Split Sections" (a demonstration), L. D. Leonard. "Spring management for comb honey," L. F. Sampson. "Putting sections on hives," Geo. W. Shafer, Menomine, Wis. "How to get well-filled sections," Jos. Moser Calmar, Iowa. "Removing sections from the hive," L. A. Stickney, Minnesota City, Minn.

"What to do with unfinished sections," C. S. Russel, Pine City, Minn. "Packing and crating honey," Peter Howe, Kellogg, Minn.

THURSDAY FORENOON.

- 9:30. "Marketing honey," P. A. White, Barron, Wis. Mrs. M. McCabe, Minneapolis; F. E. Lang, La Crosse, Wis.; Mrs. F. J. Butterfield, Long Lake, Minn.; O. J. Goodmansen, Little Falls, Minn.; Mr. Fred Oesch, Winona; L. M. Bussey, Minneapolis. "Bees and flowers," P. R. Little, St. Louis Park.
- 11:00. Beginners' hour and question-box. Mrs. J. A. DeLameter, Mrs. Mattie Watts, Mr. F. E. Halden. Mr. H. G. Brant.

THURSDAY AFTERNOON.

- 2:00. Symposium on extracted honey. "Preparing bees in spring," C. D. Blaker. What to do at commencement of honey-flow," Frank Schillock. "How to prevent swarming," C. F. Greening. "Methods of uncapping and extracting," P. C. Van Someron. "Uncapping-knives," H. V. Poore. "Why flowers do not always produce nectar," E. L. Hofmann. "Management of bees after the honey-flow," F. W. Ray, Prof. Francis Jager.

Among those present were quite a few students who are taking the course in apiculture. The following officers were elected for 1915:

Rev. C. D. Blaker, Minneapolis, president; first vice-president, Rev. J. Kimball, Duluth; second vice-president, Mrs. J. A. De Lameter, Hopkins; secretary and treasurer, F. W. Ray, Minneapolis; Executive committee, L. C. Pilcher, St. Paul; L. F. Sampson, Excelsior, and Mrs. M. McCabe, Minneapolis.

PUTTING BEES IN SELWYN'S CELLAR

BY G. F. K.

A description of Mr. Selwyn's bee-cellar at Kirk's Ferry, Quebec, appeared in the Sept. 1st issue, p. 676. The bees were carried into this cellar Nov. 15. The morning was clear, the air crisp, the temperature a few degrees below freezing.

The apiary is situated on the side of a hill, and the hives are scattered in all directions, the unevenness of the ground making a definite arrangement impossible. The hives are of the eight-frame size, some fitted

with the excelsior cover and some with a packed galvanized-iron cover. Between the top-bars and the cover are two thicknesses of cloth—the lower one of 10-oz. duck, and the upper one of burlap cut from an old sack. In some cases, where an excelsior cover was used, the moisture from the bee cluster had condensed and the cloth was frozen stiff.

The entrances of the hives—full width but only $\frac{3}{8}$ inch deep—were blocked with tissue

paper stuffed in. This proved an excellent way of closing the entrances as long as the paper kept dry; but during the morning a blizzard caused the snow to dampen the paper, and in some few cases the bees found their way out.

The hives were arranged in the cellar on long scantlings forming racks, three tiers to the row. The covers were removed as the bees were carried into the cellar, leaving only the thickness of the duck and burlap over the bees.

When all the colonies were in, the doors

were closed and all means of light excluded. By the light from a candle the entrance papers were quickly removed and then the bees were left to care for themselves till Christmas. At that time the brood-chambers were raised in front by a block of wood, leaving an entrance about $\frac{7}{8}$ inch deep.

The temperature of the cellar seldom varies more than two degrees either way, the desired temperature being 38° . The 18-inch cement walls and the sub-earth intake pipe keep a uniform temperature until late in spring.

DEVICE FOR CUTTING OUT NATURAL CELLS FOR QUEEN-REARING

BY J. H. TODD

The illustration shows you a queen-cell cutter for queen-rearing which I have designed. The method of getting cells is as follows: From the brood-nest of your selected queen take a comb containing newly hatched larvæ in the center, and with a thin sharp knife

cut out a piece of this comb containing a sufficient number of larvæ newly hatched. Return the comb, and the bees will quickly repair the damage. Now take this piece of comb indoors, as if proceeding to graft in the usual way, and, with an uncapping-

knife, shave down to the midrib the cells on the side of the comb opposite to those selected. Have a little molten wax at hand, and lay your comb midrib down on a

Fig. 2.

piece of flat smooth board; then, grasping the tin flange of the cell cup in your right hand and the wood flange in your left, pull them apart. Place the cutting edge of the tin tube exactly over a cell containing a larva of the correct age, and carefully press it down without twisting, keeping the cell in the center of the tube till the midrib is cut through; then lift up the tube containing the cell; dip the end of the wooden plug in the molten wax and quickly press it home

down the sharpened end of the tin tube. The molten wax will stick to the cell base and fix it, and will also provide a thick base for the cell. The pushing home of the plug will make the mouth of the cell project the correct distance beyond the tin flange, which in its turn will form a base for the bees to attach the queen-cell to.

The cup is placed in a holding bar in a manner similar to a Swarthmore cup,

the hole being of such a diameter that the tin flange will just pass through it, and the bar of such thickness that, when the cup is in position, the tin flange is flush with the under side of the bar.

I think the advantages of this cup are obvious. It is much more simply and rapidly prepared than by either the grafting method or the Swarthmore method, the queen laying directly in the cups; and, above all, in comparison to the usual method of grafting, the larvæ are never man handled, and these delicate little insects go to the cell-building bees without removal from their cells, and in their natural state, suspended in their chyle food just as supplied to them by the workers.

Christ Church, N. Z.

PROFITS IN TAKING BEES FROM TREES

BY ELIAS FOX

I have been reading your comments on taking bees from trees. Now, I am in no position to tell upon what your ideas are based; but they are surely not based on facts—at least as applied to my experience, which was set forth in GLEANINGS some years ago, and again in my comments upon the writings of Mr. Chadwick, of California.

As to whether or not it was profitable to save bees from trees when cut, I thought I had proven conclusively that it was; but, judging from your conclusions, Mr. Chadwick's ideas, based upon guesswork, were accepted in preference to mine, based upon a personal and practical experience; but, no matter. I know I am right, and presume I have had as much practical experience as any man in the United States, and that is taking in a lot of territory. I realize it, and I am willing to take back numbers of GLEANINGS on your file and compare notes with anybody along this line.

All of my transferring from trees to hives has been done in the fall, and most of them late at that, and as late as November 27. I have yet my first colony to lose in wintering, so taken. Many of them have given me 100 lbs. of choice extracted honey the following season, and had plenty left for wintering. Only a few years ago I cut fourteen trees in the fall, and out of the trees cut I saved ten good colonies. Sometimes a tree will break in falling where no small trees are handy to let them fall upon, and in such cases a queen may be lost or a portion of the bees mashed. At such times I doubled; but you can see that the per cent of such was small when I had ten good swarms out of the fourteen; and the beauty of it was, I had ten good colonies the next spring; and when fall came I had twenty good stocks and 1000 lbs. of fine honey.

Now, who, in the face of this, can say it is not wisdom to transfer bees from trees cut in the fall? I have never done this, simply because I have never had the opportunity; but I will bet some money that I can transfer a swarm in this manner in December or January, and save them. When you look at it from a reasonable standpoint, why not? If trees are cut after the brood is all hatched you have exactly the same conditions that you have in the hive—viz., a colony of young bees, and, as a rule, a young queen; and if properly done they stand just as good a chance to survive the winter and build up early in the season as if they were hatched in the hive.

So far as adjusting themselves to new

surroundings, it has no ill effect whatever; and I wish to relate my first attempt in this direction.

An old experienced bee-hunter found a tree that he knew was useless, sold it to a man running a hardware store in the village of Hillsboro, and the tree was in sight of the village. The purchaser asked me to help him cut it, saying he would divide with me. I told him I did not care for a division, but he was welcome to the honey, and I would take the bees and empty combs. This was highly satisfactory to him; and when we cut it and opened it up there was a little bunch of bees and a nice young queen. I actually believe a quart cup would have held every bee (though we might not have been able to get the queen in). They had two pieces of comb, a little larger than my hand, which had been filled with brood, though all were hatched. There was no honey.

The purchaser sat there on the little log, about ten inches in diameter, looking at the contents, and finally said, "Well, Elias, you know what the contract was; help yourself."

To show that I was game I proceeded to drive the little yellow-banded fellows into my box, and picked up the two pieces of comb, and away we went (on Sunday at that as that was the only time he could get away).

When I reached home I prepared a hive—I think with four frames of honey taken from an upper story, and the way those little fellows took possession was not slow. I took them to my yard, two miles from the tree, and they went into the cellar with the rest later; and when brought out in the spring they were as bright as the day they were put in.

They built the hives up rapidly, and were a nice colony when clover was ready, and at the close of basswood I extracted 100 lbs. of honey from them, and they had plenty for winter, but they did not swarm.

Now, come on, brother bee-hunters, who don't rob the bees and leave them to starve in the woods. Let us settle this question once for all.

Union Center, Wis.

[Perhaps our statements referred to in the foregoing were rather too sweeping; but we had in mind advice for beginners rather than for experts. We consider our correspondent an expert in taking bees from trees, and we believe that he can do what many others should not attempt to do along this line.—ED.]

ORIGIN OF ALBUMEN IN HONEY

Based on a lecture by Dr. Langer-Graz

BY J. A. HEBERLE, B. S.

About 17 years ago, French and German scientists, by experiment and extensive studies, worked out a method of differentiating origins. In order to understand clearly what follows, it is necessary to describe briefly some of the methods.

If into an animal a dilute solution of albumen, for instance from a hen's egg, be injected a few times, the blood of this animal undergoes a very subtle change. If blood from this animal is taken, and, after coagulating, the thick part separates, there remains an almost clear solution called serum. Through the injection the serum has acquired the peculiar property of giving a precipitate with a dilute solution from the albumen of a hen's egg, but not with albumen from other sources. It may be mentioned that the serum obtained in the above-mentioned case will not act uniformly with egg albumen from various birds. With some egg albumen it will fail to give a precipitate if the dilution is 1 to 100, 1 to 200, or 1 to 1000; while with the albumen of the same source that has been used for injection it will give a distinct precipitate if the dilution is 1 to 10,000; 1 to 50,000, or even greater. The nearer related the birds are to the one from which the egg albumen was used for injection the more dilute may be the solution of the egg albumen and still give a precipitate. This biological method furnishes the only means to decide the derivation of albuminous bodies, and is used in food analysis and by court chemists. By this method blood spots, even if old and dried up, can be positively identified, whether from the human body or lower animals.

Prof. Langer began to use the biological method for the critical examination of honey in 1902. At the same time, and independently of him, von Riegler, of Budapest, worked on the same problem. Prof. Langer used albumen derived from honey, while Riegler used a dilute solution of honey for injection. The obtained serums gave precipitates with dilute solutions of honey. The results of several years of study and experiments were published in the *Archives of Hygiene*, 1909. Prof. Langer has determined that the albumen in honey is derived from the bees. Animals that have been treated with albumen derived from honey furnish a serum that gave a precipitate, not only with honey albumen, but also with watery extracts from the heads of bees, the larvæ of bees, of bee-bread, and with diluted chyle. Animals treated (injected)

with watery extracts of the heads of bees furnished a serum which gave a precipitate with honey albumen. These reciprocal reactions pointed to the presence of a uniform albumen in honey, the heads of worker bees, larvæ of bees, bee-bread, and in chyle.

Prof. Langer's endeavor to prove the presence of albumen of vegetable origin in honey by the biological method was not successful. He recommended a detailed method for the quantitative determination of albumen in honey, and asked that it be thoroughly tested. Two scientists have reported, and the results obtained agreed with his. Especially valuable was the report of Dr. Thoeny of the Swiss health office.

Dr. Kuestenmacher, in 1910, gave it as his opinion that the albumen in the honey comes from pollen. According to his idea, the albumen of the pollen is dissolved in the pollen-stomach, and diffuses partly through its walls, and so becomes chyle, and part of it (the albumen of the pollen) gets into the honey. The mistake of Prof. Langer, writes Dr. Kuestenmacher (that the albumen in bee-bread gets into it with the saliva of the bees) I need not refute, because I have shown elsewhere the principal parts of which pollen consists, exclusive of saliva.

Prof. Langer was much interested, and either wanted to prove the assertion of Dr. Kuestenmacher (that the albumen in the honey was derived from the pollen) or disprove it. He gathered pollen himself from the hazelbush, and made a watery extract from the whole pollen as well as from pollen after triturating it with fine sand. With these dilute solutions rabbits were injected, so he obtained a pure pollen (anti-serum). This gave a precipitate with a very dilute hazel-pollen extract with other pollen extracts, only in more concentrated solutions; but it gave no precipitate with honey albumen. Dr. Kuestenmacher claims that honey albumen is a pollen albumen. If that were so, a serum obtained by injection with honey albumen would give a precipitate with pollen albumen; but Prof. Langer never succeeded in obtaining a precipitate under these conditions.

According to the results of his extensive experiments he concludes that the mistake about the origin of albumen, at least of the biologically tangible albumen in honey, is on the side of Dr. Kuestenmacher.

The experiments of Dr. Langer force one to the conclusion that the albumen in honey is derived from the bee.

Kempton, Bavaria, Germany.

KOOTENAY BEEKEEPERS' ASSOCIATION, BRITISH COLUMBIA

BY W. J. SHEPPARD, HONORARY SECRETARY-TREASURER

A well-attended and enthusiastic general meeting of the newly formed Kootenay Beekeepers' Association, the first one of the kind to be organized in British Columbia, was held at the City Hall, Nelson, Nov. 27, for the purpose of electing officers and passing a constitution and by-laws. The meeting was also a thoroughly representative one, beekeepers from many of the outlying districts of the east and west Kootenays and boundary, the territory covered by the association, being present.

It has been recognized for some time that, in order to stimulate the beekeeping industry, and assist beekeepers in disposing of their honey, a system of co-operation has become absolutely necessary. Since honey of uniformly good quality in any quantity is capable of being produced in this section of the Province it could not be expected that it would be possible to dispose of it at remunerative prices unless a uniform system of putting it up for market could be provided. The beekeepers have also had considerable difficulty in the past in obtaining bee-supplies, owing to heavy freight rates and other causes, and also to get hives suitable to the climatic requirements of this region. Thousands of fruit-trees have been planted all over the territory during the past few years, and for this reason alone the keeping of bees has become essential. It is hoped, therefore, that the association will be able to accomplish useful work. That the movement is appreciated can be gauged by the fact that nearly half the beekeepers in the territory have already become members and paid the annual subscription of \$1.00.

The objects of the association as set forth in the constitution and by-laws adopted at the meeting are as follows:

The objects of the association shall be to promote and encourage the keeping of bees and the most suitable methods for their profitable management.

To assist members of the association in disposing of their produce to the best advantage by the adoption of uniformity in its "getup" for market, and the provision of a special distinctive honey-label, for the use of members only, which should ultimately tend to be looked upon by the purchaser as a guarantee of excellence and purity.

To obtain the most advantageous terms for members in the purchase of bee-supplies.

To promote and regulate local exhibitions of honey and other bee products, and arrange for the competent judging thereof.

To advocate the more general growing and cultivation of nectar-yielding trees and plants, such as linden or basswood (*Tilia Americana*), alsike clover (*Trifolium hybridum*), etc.

To aid in the dissemination of reliable and practical information with regard to the beekeeping industry, and further its progress in every way possible in the interests of the members.

The following officers were unanimously elected for the year ending September 30, 1915:

President, G. Fleming, Nelson; vice-presidents, James Johnstone, Nelson, and Major-General Lord Aylmer, Queens Bay; honorary secretary-treasurer, W. J. Sheppard, Nelson; executive committee, J. J. Campbell, Willow Point; Mrs. Casler, Nelson; J. Hyslop, Nelson; C. G. Johnson, Nelson; W. H. Rixen, Nelson; W. J. Mohr, Nelson; J. Blinco, Creston; B. Lockwood, Fruitvale; E. Alpaugh, Kaslo; R. E. Plewman, Rossland; J. H. Vestrup, Nakusp; H. W. Collins, Grand Forks; H. G. Slater, Robson; T. S. Gill, Cranbrook; G. F. Attree, Queens Bay; Auditor, J. D. Kerr, Longbeach.

White-haired Beefolk

BY GRACE ALLEN

On a vacation ramble among the Tennessee hills more than thirty miles from a railroad, we came upon this charming couple, aged seventy-six and sixty-six respectively. In an orchard on their farm were about fifty stands of bees, in old-fashioned "gums."

In their cottage yard we found them,
Back among the trees,
White-haired beefolk on a hillside,
With their countless bees
Humming happily around them,
And a quiet calm
Like an ancient benediction
Or a psalm.

Now when crowded days come bringing
Tasks that never cease,
We recall the gentle beefolk
With their steadfast peace,
And we seem to hear a singing
On a far-off hill,
Where our spirits pause and listen,
And grow still.

Fall negligence and wide entrances only lead to winter tragedies.

Report of the Minnesota State Inspector of Apiaries

St. Paul, Minn., Oct. 10, 1914.

The Hon. A. O. Eberhart,

Governor of the State of Minnesota.

Dear Sir:—The Inspector of Apiaries herewith submits his fourth annual report, as required by law, and shows:

Number of apiaries inspected, 374; number of hives inspected, 6975; number of apiaries found diseased, 33; number of hives found diseased, 197; number of apiaries given treatment, 27; number of apiaries reinspected, 24; number of hives found incurable and destroyed, 47; number of empty hives disinfected, 25; number of box hives transferred to movable-frame hives, 13.

The above apiaries were found in the following counties: Benton, Blue Earth, Carver, Chisago, Dakota, Faribault, Fillmore, Goodhue, Hennepin, Houston, Le Sueur, Meeker, Pine, Ramsey, Rice, Sherburne, Stearns, Wabasha, Waseca, Washington, and Wright.

In my last report I discussed the discovery and treatment of "foul brood." I shall, however, make my report for this season as brief as possible, showing mostly the work that my deputies and I have accomplished.

The bee industry in the State of Minnesota has been nearly a total failure this year, the spring having been unusually wet and cold. There are a few places showing surplus honey, but in the majority of

apiaries feeding has been necessary. This state of affairs makes it very unpleasant for both the beekeeper and the inspectors.

I am pleased to say that the treatment for foul brood has been a great success. We have worked hard to stamp out this disease, although we have encountered many difficulties in so doing. Permission to inspect several apiaries has been refused me this season at first, but a little patient instruction won over the beekeepers. The State law provides, of course, for compulsory inspection, but sometimes it is a little hard to make the keeper understand its benefits.

We certainly have a good law in this State. I have received requests from bee inspectors and agricultural colleges all over the country, asking for copies. The beekeepers of Minnesota have reason to be proud of this fact.

I expect to see a better honey crop next year, as conditions look very promising all over the State at this time.

Respectfully submitted,
J. ALF. HOLMBERG,
State Inspector of Apiaries.

Bees Come to Montreal as Stowaways

The record for freak stowaways belongs to the steamer *Montezuma*, which made port on the morning of July 22, with a good swarm of bees on board. Italian bees they were, and it was across a belt of salt water four miles wide the busy workers came when they decided to leave the European field and seek the gardens of the New World. When they arrived on board the big cargo boat, three weeks ago, they were hospitably received by Chief Engineer Stanley. They swarmed around one of the boat davits, on the after deck, where Mr. Stanley hived them in a soap-box. Since that day the bees have worked like Trojans. Their diet has been sugar and water, and whatever jam they could purloin from the ship's galley. On the warm days they were all over the ship. Mr. Stanley states that several scouts have gone out to investigate the neighborhood, in spite of the cold. When the sun comes out they will travel further afield, but no fear is felt that they will swarm off, as they seem to be very comfortable.

The bees will make the return trip in the same box, and then will be sent to Engineer Stanley's home in Wales. Mr. Stanley states he has not been stung during the voyage; and when showing the hive the bees walked all over him.

The *Montezuma* is the largest cargo boat running to Montreal, having a full capacity of 12,000 tons. Three and a half years ago she broke the Canadian record for immigrants, carrying 2618 in one trip to St. John's. Her cargo is general from Antwerp. At the time the *Gothland*, on the Scilly Islands, ran aground, the *Montezuma* was not far behind, and was one of the vessels to respond to the S. O. S. call.

The Effect of the War on Honey Prices in Scotland

I am in the best clover district that can be had, but I am going to a poor clover district, but one where there is miles of heather. It is only a year, now and again, that it is possible to get a big yield of heather honey, and 1914 was such a year.

The war has been greatly against the selling of honey. Shops are not buying nearly as much, for they have no one asking for it. The price has been very low.

JAMES SMITH
Drungans, Newabbey, Dumfries, Scotland, Nov. 9.

Ventilated Coat Sleeves

In the sketches herewith I illustrate a ventilated wristlet, or cuff, made of wire fly-screen, connecting the gloves to the sleeve of the coat, or connecting the gloves with gauntlets, to enable the wearer, when handling vicious bees, to enjoy cool arms and hands in consequence of the free circulation of air about the bare wrists. The wire-screen wristlets protect from the stings of the bees by being held away from the bare wrists half an inch or more by the half-inch spiral coils of wire soldered or substantially fastened to the wristlet, as shown in Figs. 3 and 4.

Fig. 3 shows the wristlet straightened out flat with the half-inch spiral coils of wire attached in the best shape for sending through the mail.

Fig. 1 shows a work coat fitted with ventilated wire-screen wristlets or cuffs. Fig. 2 shows a gauntlet glove similarly fitted.

I have used a coat fitted with wire-screen wristlets or cuffs as shown in Fig. 1 for the past several years when handling vicious bees during hot dry weather after the end of the honey-flow, and find it immensely more comfortable than a coat without them, having the gloves sewed directly to the sleeves of the coat.

An Outdoor Colony Put in a Hive Nov. 15

A man while hunting, Nov. 4, near my apiary, saw four pieces of comb on an oak-tree, and found a swarm of bees on a little bush about 30 feet away from the oak. It was a cold night, and the tree stood by itself in an open field. The bees left the combs to go to the bush, no doubt to get out of the wind.

On Nov. 5 I hived the bees and gave them combs of honey. The combs on the limb of the tree were about eight inches across, while one was smaller. This is the first time I ever hived a swarm in November.

Last season, which was very dry, with 17 colonies of bees I secured about 800 pounds of honey, mostly extracted. My apiary is at Remington, Va., and I work in Washington, D. C., 57 miles away, so that I do not see my bees in the summer oftener than once in every three or four weeks. I had no swarm in 1914. I keep my queens clipped.

Washington, D. C.

F. TAYLOR THOMPSON.

Bees on Shares or for Rent

I desire some information concerning what is considered as a fair and safe proposition to make to the owner of an apiary for its rental.

Houghton, N. Y., Nov. 28.

H. R. SMITH.

[When bees are put out on a rental basis, or on shares, the party who furnishes the bees receives half the honey and beeswax and all the increase, while the party who furnishes the labor receives half the honey and the beeswax, but no increase.

If he participates in the last mentioned he is inclined to run the bees for increase and not for honey. He will, therefore, keep the increase down as much as possible and run the whole for honey. For fuller particulars you are referred to "Bees on Shares" in our A B C and X Y Z of Bee Culture.—Ed.]

A 20 x 20 Thirteen-frame Hive as Standard

A subject of especial interest is that of a larger hive, under discussion in the last two numbers of GLEANINGS. I believe that honey-producers quite generally are arriving at the one opinion that the ten-frame hive is too small. The eight-frame is not worthy of mentioning as a beehive. It may do for a home for a nucleus for a short time. I believe that the eight-frame hive is the direct cause of excessive swarming in this locality. I believe that a standard size should be agreed upon, and manufactured as a standard by the supply-houses. This, perhaps, would be hard to agree upon, as at present there seems to be a great diversity of opinion. To my

mind it seems that the square hive, 20 x 20 inches, containing 13 L. frames, would make an ideal standard hive. True, many of our best queens under proper care would fill a larger hive; but with this hive it would not require any great amount of manipulation to keep ahead of the most prolific queen.

In the past few years more than half of my queens under stimulative feeding (one-half pint warm sugar syrup each evening from the close of fruit-bloom until the opening of clover bloom) have filled from fifteen to twenty L. frames with brood before the clover bloom opens. What we want is a hive that will provide plenty of room for breeding to the limit of their strength, assist in curtailing swarming, provide a good honey-producing hive, and at the same time prove a good winter hive without excessive manipulation. This 20 x 20 square hive, it seems, will strike a happy medium for breeding, honey production, and summer.

For winter, furnish it with a telescope top ten or eleven inches deep, and large enough to allow half-inch packing on all sides and a heavy packing on top under cover. This, I believe, will make an ideal hive for outdoor wintering. While brother Hand makes a good plea to cut out excessive manipulation, it seems to me that his sixteen-frame hive with an eight-frame inside for winter, with sixteen-frame super added, requires about as much manipulation as any plan I know of in use or advocated by any one else.

Removing the queen together with two frames of brood at the beginning of the honey-flow, to prevent swarming, works very successfully in preventing swarming, giving a good honey yield and an increase of 100 per cent with a ten-frame hive.

Urbana, Ohio.

O. J. JANES.

Sections Stamped with Too Low a Weight

We were much interested in reading the article on page 221, Dec. 1, on the net-weight law as applied to the comb-honey business. Both your comments and those of Mr. R. A. Burnett, of Chicago, meet our views. We think that if the beekeepers would take a little more pains and very little more labor they could comply with the law, and the results would be more satisfactory to them and to the dealers. As Mr. Burnett says, "make the sec-

tions more equal in weight in each case." For instance, we handled a car of comb honey this fall in which there was entirely too much difference in the marked weights of the sections and the actual weights. We found sections marked 8 ounces when they actually weighed on the scales from 13 to 15 ounces. This was the way with the majority of the cases in the car. If these sections had been marked 12 or 13 ounces, the law would have been complied with, and the honey sold for more money. About the first question our customers ask us when we offer honey for sale is, "What do the sections weigh?" We open a case, showing a section marked "8 ounces," and the customer says, "Too light weight;" consequently it is difficult to get all the honey is actually worth if it had been properly marked. Eight ounces complies with the law all right; but the seller gets less for the honey than if it were marked correctly.

We think that this is really an unnecessary law, and the benefits the beekeepers and the consumers will gain will not be equal to the expense and labor, and the consumer will pay just as much or more for the honey; but it is the law, and all concerned must make the best of it.

Binding Magazines with Nails

No doubt many of your readers feel an interest in saving copies of GLEANINGS for reference, but do not wish to go to the expense of buying binders or having them bound. In the following method I find a good and cheap way to keep them, and have them always arranged for ready use. I find that twelve numbers, or half of the year, make about the right number for putting together. Select these and make the backs and bottom edge even by holding the lot edgewise on the table; also make sure that you have them arranged properly.

Now use eight nails of the size for nailing frames together, also eight small pieces of oilcloth or thin leather about $\frac{1}{2}$ inch square. I find that oilcloth doubled to make the size is best.

Drive the nails about $\frac{1}{4}$ inch from the back edge of the bunch of numbers selected, four to each side, making use of the oilcloth pieces to prevent the heads of the nails from sinking into the paper and tearing out later.

Four of these nails will lack just a little of going through, and the four driven from the other side will make the binding complete, so that you will have your numbers easily bound, and they will not come apart.

This will also apply to the other bee-journals; but I find that the twelve numbers, or full year, can be put together.

Shellman, Ga.

D. W. HOWELL.

A Bid for National Association Advertising

Mr. Editor:—Judging from quite a number of letters we have had from beekeepers in various parts of the country we imagine that, when the National Association meets in February, there will be some discussion about advertising, as there has been for years, and especially as to the use of a page of reading-matter relating to honey in the *American Grocer* each fourth week during one year—13 times—to show grocers that they can sell more honey.

The writer for a long time has been firm in the belief that the consumption of honey in the United States might be largely increased, and a good point to start with is the grocery trade—not that the *American Grocer* covers the whole fraternity, but it is the oldest (and we believe it to be the most carefully read) paper of its class—one eminently worthy of the support of the National Association. The cost of this page per member of the Association will be

a mere bagatelle—so little, indeed, that an outlay five times as large would not be burdensome, and thus other publications might be used too. If the National Association frowns on the use of this journal, we believe there are individual beekeepers who will use the space—being willing to place the whole burden on their own shoulders—just as in some churches some "pillars" seem willing to "pay the freight" for the benefit of the whole body. I should like to have the opinions of your readers as to this project. The cost for the 13 pages will be \$30 for each insertion. If we may be trusted to do so we will get up the matter here, though we by no means insist on doing the work.

THE AMERICAN GROCER,
per F. J. Root, Adv. Manager.

New York, Dec. 9.

Bucher's Drawer Feeder

I am sending a sketch of a feeder. I do not know that it is new, but it is the most satisfactory of any of the different feeders I have tried. The case is made the width of the hive, and three or four inches longer, to provide an alighting-place. There is a bee-space left all around the drawer inside the case so that no bees can be killed in opening and closing the drawer. The drawer is provided with thin strips spaced about $\frac{1}{2}$ inch apart to prevent bees from drowning. Of course the depth of the drawer will determine the amount of feed it will hold. If a strip with a hole for pouring syrup is fastened against

the drawer end, flush with the top of the sides, with wire screen tacked over the hole on the under side of the strip, no bees can get out while feed is given.

As an experiment, on June 13, 1914, we took an old box hive that had cast a swarm about 17 days previously, and drummed the bees out, making sure of the queen, then dumped them in front of the entrance of a new hive filled with full sheets of foundation, except one frame of honey (our honey-flow had ceased at that time). The old hive was then set close to the rear of and connected to the new hive with a tube and Porter bee-escape in such a way that the remaining bees in the old hive on coming out were compelled to pass through the tube into the new hive. In three or four days practically all the bees were in the new hive. Then they were set over the feeder, and their stores fed back by simply filling the drawer with the old combs. When the first batch was clean, the drawer was refilled and so on. In a short time those bees were in a new hive, with new straight combs, without the disagreeable mess of trying to fit old crooked combs in frames, and a poor job in the end.

Littlestown, Pa., Sept. 15.

C. F. BUCHER.

The Net-weight Law a Nuisance

The net-weight law has caused me no end of trouble. I sent for three rubber stamps, and marked all my sections that weighed $12\frac{1}{2}$ oz. or more. However, R. A. Burnett, of Chicago, says that every section weighing within an ounce should be cased

separately. This would mean that I would have to have several more stamps to mark the different sections. If one case has its sections marked $12\frac{1}{2}$ oz., and another 14 or 15 oz., I am afraid that the case marked $12\frac{1}{2}$ oz. would not bring the price the other would; yet the one marked $12\frac{1}{2}$ oz. may be No. 1 comb honey.

Plum City, Wis.

H. E. LUECKER.

Beekkeeping in Texas

We began work about the first of March, going through the colonies which had come through the winter in fine condition on the summer stands. We found many of the brood-chambers so full of honey that the queens had very little room to work.

We take out one or two frames of honey and put foundation in place of the honey. If we have any weak colonies that seem to need help in the beginning of spring we take honey, and sometimes brood from the strong hives, and give to the weak ones; then about the time the huajilla is beginning to bloom we put two weak colonies together, one on top of the other with a newspaper between them, so we have all colonies *strong* at the beginning of the honey-flow.

We store the frames of honey taken from the hives in early spring in the honey-house; and as we have the swarms we give each swarm one or two frames of honey. We always wait until near night to do this work, so we have no trouble with robbers. Our bees usually gather enough honey from the persimmon and prairie flowers for brood-rearing through the early spring. The huajilla is the earliest bloom that we get any marketable honey from. Then comes the catclaw. These are the main sources for our crop in this country. Some years we get some honey from horsemint, whitebrush, and some few other flowers that yield very good honey in early summer.

We had a fine huajilla bloom last season. Just as that was giving out, the catclaw bloomed—the finest crop of bloom we ever had; but the rainy weather set in and cut the crop from that source short.

We got 12,000 lbs. from our two apiaries—185 colonies in all—mostly bulk comb honey. We have about 3000 lbs. of that on hand yet.

PREVENTING GRANULATION OF BULK COMB HONEY.

We heated the extracted honey that we packed our comb honey in. We heated it very slowly, and kept it hot a long time. We did not let it get to the boiling-point and did not spoil the flavor nor turn it dark, and none of it has granulated so far.

We had a broomweed bloom last fall, and had no cold weather, but a good deal of rain. The hives filled up rapidly, giving a crop of that off-grade honey to extract. It is worthless, as there is so much of the better honey on the market.

We went to the apiary a few weeks ago and put some foundation in the brood-chambers—on the average one frame to the colony—so that we would have more combs to hive swarms on in spring instead of so much of the off-grade honey.

Del Rio, Tex., Nov. 26.

MRS. C. DISHMAN.

Queens and After-swarms

Last season my whole yard swarmed at once, about 150 colonies in ten days. Much mixing occurred. I feared there would be many queens missing for that reason, and because there was a pest of bee-martins. The swarming took place during a heavy honey-flow from alfalfa. There were many after-swarms, having from two to six well-developed virgin queens. I proceeded as follows: Putting a few queen-cages in my pocket, with the ends closed with wads of cloth, I took a dishpan to where the swarm had settled, and shook the bees into it. I picked out the virgins and caged them, shaking the bees about as necessary, then took the pan to the middle of the yard and threw them into the air. I mated the vir-

gins in Rauchfuss nucleus boxes holding three common comb-honey sections, and when inspecting for fresh eggs I introduced them into the queenless colonies, which were 15 in a total of 270 in the apiary.

I do not claim this is the way to raise the best queens, though I fail to see in what way they are inferior to any of those left in the hives after natural swarming. It did, however, take care of the queenlessness, and also put the bees of the after-swarms back where they belonged.

Zapata, N. M.

H. H. BROWN.

A New Way to Stop Robbing

Find the colony which is *doing* the robbing, and cover it over with old carpet or burlap, or grass or weeds. Leave its entrance wide open and tuck the sacking down close under the hive so those out will have much difficulty in finding their way into the hive. May be they will not get in. There will be something doing around that hive within a few minutes. Leave it that way for an hour or two. The colony will come to no harm, even on the hottest day here.

Also go to the colony being robbed, and smoke slightly and close the entrance for a minute and pound the hive; then open the entrance for a few minutes. The robbers will all leave quickly. Then contract the entrance to two bee-spaces and leave for a day or two, and you will have no further difficulty. This method has never failed here. I have never seen this in print. May be it will help some one.

Vincent, Ohio.

W. S. BASIN.

Terrible Fire in California

On Nov. 19 we had one of the worst fires here in the mountains ever known. It burned a strip 5 miles wide and 30 long. The people had to run for their lives. I lost 90 stands of bees, my bee-house, eight-frame extractor, gasoline-engine—in fact, everything I had. I was living in my honey-house, and I even lost my bed and bedding, cooking utensils, 367 empty hives and frames. Besides mine there were two houses and a barn burned and six head of horses, and five deer.

Arroyo Grande, Cal., Dec. 9.

M. D. PRICE.

[GLEANINGS extends sympathy. A disaster of this kind is terrible indeed.—ED.]

Queen Accepted after Cells were Started

I have had good success with direct introduction of queens with smoke, although I had three failures which I cannot account for. I had also a rare experience. To a populous colony of cross hybrids in a two-story hive I introduced a queen. On the fourth day I examined the colony, and found numerous cells started. I grafted them all. On the third day I examined to see how many accepted. Not one cell was in existence, and I found the queen introduced all right.

C. M. CARMONA.

Trinidad, British West Indies.

Bee Martins—Do They Do Damage in a Honey-producing Yard?

Would you kindly advise whether it is advisable to do away with martin-houses near an apiary? We love to have these birds on our fruit-farm; but I am not sure that they may not do serious harm to our bees. Some claim they eat drones only.

Chicago, Ill., Nov. 17.

T. H. HOLMES.

[There is a bird, known as the bee-martin, that kills bees and queens; but unless you are rearing queens in considerable numbers, we do not think you need to pay any attention to the birds, as the few bee-martin houses that you have there will do no appreciable damage.

Yes, these birds eat drones; but they are also fond of queens. —ED.]

A. I. Root

OUR HOMES

Editor

But I say unto you, that ye resist not evil.—
MATT. 5:39.

Pray for them which despitefully use you, and
persecute you.—MATT. 5:44.

Some of you may, perhaps, feel like saying, "Why, brother Root, you have had the above text over and over. Can't you think or talk about something else?" No, friends. I cannot think or talk about something else when this same "Gospel of Christ Jesus" is still such an "*unexplored region*" as I told my good mother years ago.

About the first thing on reaching our Florida home was to see if the Sears automobile was in good trim after standing unused six months in the auto house. It went off promptly on almost the first cranking. Have you forgotten about the mischievous boys who vexed and annoyed me two years ago? Well, if you have, the boys haven't. Just as soon as I stopped before a store, two of them, with mischief in their looks, pounced on my auto, began pinching the tires, blowing the horn, and pulling and twisting almost every thing movable. The impulse to forbid them touching my property was almost irresistible; but (thank God) I had learned some lessons. I took no notice of them, and started to go into the store; but as I neared the door and heard them rattling things the temptation was so great to look around and *see* what they were at I could hardly stand it, and could only mentally groan in distress, "Lord, help!" I think I added, "O Lord, give me faith to believe *you* will not only take care of my machine but of my poor self also while I am *trying* to follow your commands."

Years ago, when I was laboring in the Medina jail with my poor friend "Fred," he said that, while this new doctrine might be right, it "went awfully agin the grain," and I realized it.

When I came out of the store they had stopped meddling (my prayer was promptly answered, please notice), and I said, as if nothing had annoyed me:

"Boys, can you tell me where Roy Parker's place is?"

"Oh, yes! we'll show you. Sha'n't I crank your machine?"

As he was a small boy, and hardly equal to the task, his companion laughed at his apparent failure; but I gave him some instructions; and when off it went I asked them to get in and ride with me, and we parted the best of friends.

Dear friends, the above is only a trifling incident. Why should I take pains to tell

it at all? Because it embodies a great truth. These boys were simply wanting something to do. I succeeded in diverting them from their mischief into something useful. They are a fair type of boys all over our land. In our recent temperance crusade the question was asked, "Which is of more importance—the *revenue* or our boys?" Also, "Shall we pay the revenue by *sacrificing* our boys?"

A year ago two of my auto tires were punctured while my machine was left some time on the street, and how did I know that my tires would not be punctured again while I was in the store trading? It *did* occur to me; but I answered Satan that saving these two boys was of far more moment than many "tires" or even a *whole automobile*.

Very soon after our arrival a boy's face on the street startled me, and I soon recalled it was the boy who (by God's providence) I saved from a watery grave.* He is now bringing me every evening the Bradentown daily paper. In answer to my prayer, God gave him back to life, and a further responsibility rests on my poor shoulders. Is it not of far *more* importance that I win him to Christ Jesus and *everlasting* life? Whenever I meet him his face appeals to me as if there exists a sacred relationship between us. Does it not behoove me to feel a greater interest in *all* the boys because of that incident?

A word more about being in *haste* to "resist evil." Do we who are church members remember as we should that "a soft answer turneth away wrath"?

Mrs. Root and I were once riding with our old pastor, Rev. A. T. Reed. The livery horse balked. Mr. Reed said, "Wait a minute." He jumped out of the buggy, unbuckled the "belly-band," and quickly buckled it up again, "chirruped" to the horse, and off we went all right. In answer to our surprised request for explanation for such an absurd remedy he replied:

"My act simply diverted the attention of the horse from his ugly spell; and when I got back into the buggy and told him to go he had forgotten about being contrary."

* A few weeks ago I attended a moving-picture show that is attracting much attention just now—John Barleycorn. It seems "John" became discouraged in the effort to break away from his foe; and while partly intoxicated he attempted suicide by jumping off the dock. His struggle in the water, and failing strength as he made his last faint struggle when he rose the last time, were so real it recalled the incident of the drowning boy so vividly that I involuntarily started before I recalled *why* the scene affected me so.

Are we not much like the dumb brutes in this respect? The boys were surprised (and disappointed) because they did not get the scolding that would naturally follow; and finally (like the horse) they forgot about the mischief they had planned. When you learn to love your enemies you will have the "happy surprise" of finding they are enemies no longer, but friends.

I have just read in the daily of two men who got into an argument about the war. It ended by both drawing revolvers and riddling each other with bullets. Will any one explain what was settled or accomplished by this silly and wicked act? When I was a boy, skeptics made fun of the stories in the Bible about being "possessed of devils." Were not these two men *possessed of devils* to do this? and would it be so very preposterous to suppose *whole nations* are *just now* in enthrallment of "legions of devils"? How does it come these two men had revolvers, defying the law against concealed weapons? and does not the incident point out the worse than folly of equipment for war that runs up into *many millions*?

HOMELESS BABES AND "BABELESS" HOMES.

On these pages I have often spoken of the efforts that are being made to save the babies that have been so long dying in infancy, and dying for want of intelligent and proper care. A few days ago an agent of the Ohio State Board of Charities spoke at our church about fifteen minutes just before the sermon. His business is to look up the orphaned babies of the State of Ohio, or babies that have no parents or relatives to give them proper care. That is one part of his business. The other part is to hunt up fathers and mothers who have no babies or little children of their own, and who are willing to take a child and give it proper care. Let me digress a little right here.

Somewhere in this big wide world is a boy eighteen or nineteen years old. When he was born his mother was unmarried; but his father was rich enough to hire her to "keep still;" and the baby was sent to an Ohio infirmary. Perhaps we had better call it an Ohio "poorhouse" on this occasion. When this boy got to be old enough to be of some use in choring, etc., a well-to-do grasping farmer agreed to take him. I think he was "bound out" to the farmer, for that is what they called it then. Well, the agreement was that the boy was to have board and clothes, and a certain amount of schooling. My attention was first called to him when he was about fifteen years old.

He was strong, and able to do a man's work, and *had* been doing it. But he had no wages, and was sent to school so little, with so many interruptions, that his schooling amounted to about nothing. He ran away, as many another poor boy has done, and changed his name so his old "tormenter" could not find him without trouble. I consulted an attorney, and set the boy at work. He was so willing, and put in with such energy and vigor, that it really touched my heart. Well, so many cases of this kind have come to light by investigation, that the State of Ohio (may God be praised) has appointed a "commission" of men and women, first to visit the homes of those who are willing to take a child and see what sort of home it is, and what kind of people they are. Then at regular intervals the home is visited *again*, the child looked after and interviewed, to see if he has a fair chance. My friend, did you ever consider that every baby in our land, boy or girl, has a right to live and have reasonable care? The responsibility rests on you and me. From the moment a child is born under the American flag there is, thank God, a right invested in *him* or *her* to "life, liberty, and the pursuit of happiness;" and if the circumstances of the child's birth have not given him this fair chance, you and I are responsible for it. Please recall the words of the dear Savior when he said, "Inasmuch as ye have done it unto one of the least of these my brethren, ye have done it unto me."

Of course, the speaker's talk that Sunday morning reminded me of the picture on page 76 of our issue for January 15th last. Dear friends, I have had no end of kind words for that article. If you have a copy of GLEANINGS handy, of that date, it might be worth your while to look it up; and after you have looked it up, read the letter below:

STATE OF OHIO,
BOARD OF STATE CHARITIES,
1010 HARTMAN BUILDING, COLUMBUS.

My dear Mr. Root:—I thank you for the courtesy you extended to me Monday, and also for your willingness to mention Ohio's children who are in need of mother love in your GLEANINGS. I am very much interested in the article you gave me which contained the story of the deserted baby. It reminded me somewhat of a little one whom I carried a long distance in my arms on the train (and who cried almost the entire distance). She had been picked out of an ash-barrel one January morning. A woman in the morning heard a sound that she thought was a cat. On examining the debris and garbage she discovered this beautiful little two-months-old baby nearly dead from exhaustion and neglect. The little one was placed in a beautiful Christian home, and has been legally adopted. The house she lives in to-day cost nearly \$40,000. She is a splendid fine little girl of fifteen, and has brought great sunshine into the lives of her foster parents.

I was also interested in your article concerning your trip from Florida with your wife. I think I

have a strange feeling of respect for a man of your age who speaks and writes so tenderly of his wife. Of course it ought to be the rule, but it isn't.

With best wishes for the success of your Christian and humanitarian work that you are doing in connection with your business, not divorcing them as some men do, I am

Yours sincerely,

C. V. WILLIAMS,

Director Children's Welfare Department.

Now, if any citizen of the State of Ohio

who has read the above knows of a baby neglected and uncared for, will he please notify the writer of the above letter? and if you are willing to *take* a baby, or know of somebody else who would do so, send the names to the same address. May God help us in our efforts to care for the homeless babies.

HIGH-PRESSURE GARDENING

DASHEENS UP TO DATE.

Our neighbor, Mr. Stanton, got a peck of tubers of us last April, from which he has raised ten bushels. On a part of his ground that was damp black muck he got a good full peck from only one hill, and this hill came from a single small tuber. After seeing the peck of tubers I came home and had Wesley dig one of *our* best hills, and we got a heaping *half-bushel*. How is that for reducing the "high cost of living"? Are they as good, and will they really take the place of Irish potatoes? There is a "draw-back" to the dasheen as food. Once in a while you get a hill that has the wild untamed "acridity." The government bulletin mentions this, you may recall, and recommends baking soda as a corrective. We, in our own home, have never got hold of such; but Huber and his wife had one hill of our raising that "stung their throats" quite badly. Mr. Stanton says they have also had one such experience, and the women folks since then are prejudiced against the dasheen; but as for himself he wants them *every* meal instead of Irish potatoes. He expects to plant his whole ten bushels.

There is just one other fault. When baked we occasionally get a tuber, or more frequently a corm that is tough and watery, and won't bake so as to mash up dry and floury. Sometimes a small part of a tuber, say one end, will be like this; but when stewed we have never noticed any such trouble.

Another neighbor, Mr. D. Abbott, a bee-keeper, has perhaps 100 bushels of fine matured tubers, and I would advise the friends who want seed to correspond with him. As for myself I still consider a nice baked dasheen (such as we have just had for dinner) as far ahead of any sweet or Irish potato.

So far we have not succeeded (so far as I recall) in getting any tubers to go across the ocean without spoiling. It seems to be because they cannot have sufficient ventilation in the mail. They go to California and other remote States, but not to foreign

countries. Now, while this is true I have dasheen growing in our garden, the tubers of which were sent me from South Africa. See p. 471, June 15, 1913. I cannot recall now how friend Thompson packed the tubers; but *he* may recall when he sees this, and let us know.

TREASURE ON EARTH, AND TREASURE IN HEAVEN.

I have a walnut-tree that is a very strange one. It is a cross between a franquette and an English walnut. This tree is 11 years old, and never puts forth a leaf until July 2 or 3, and then it will grow two or three feet of wood, and harden up the wood for winter so frost will not freeze it. It bore four nuts last year. We ate one, and found it finer than any nut we ever saw before. We planted the three remaining nuts, and now we have two little trees from the three nuts. Now, Mr. Root, would you like to have me send you one of these trees this fall?

I am doing some experimental work. I have a chestnut grafted on to a black oak. It bore chestnuts the second year after grafting. They are good, and the tree is full of burrs this year, and promises a large crop of nuts.

Let me tell you something else. You are the cause of me and my family going to church here; and now we have a nice Sunday-school, of which I am the superintendent. The people here have tried to break it up, but I am in it to stay.

Pine Grove, Cal., Aug. 13. GEORGE PRESTON.

Many thanks, my good friend, for the offer of a walnut-tree. In our Florida home, I have several walnut-trees, and perhaps you had better mail yours to me there, as the climate is more like yours in California.

May God abundantly bless that Sunday-school and its superintendent. Such work may not be treasures laid up on earth, but it is treasures in heaven that can never be taken away.

GREEN CORN; MAKING IT MORE DIGESTIBLE.

Friend Root:—Did you ever use a corn-scratcher on your green corn? If you have never used one you would find a very decided improvement in the corn, and find it much more digestible, as you do not get any of the hulls of the corn. I do not remember seeing you mention it, so I concluded you had not.

Oregon City, Ore.

H. A. BLV.

My good friend, I thank you especially, as I have noticed green corn sometimes distresses me, and it occurred to me these tough hulls are difficult of digestion. I now recall seeing such a "scratcher," as you call

it, once, in the home of a relative. As I remember it was a little brush of sharp steel wires. Can any one tell us where to get the implement?

SWEET CLOVER THE SUBSOILER.

We clip the following from *Farm and Fireside*:

Sweet clover is one of the best miners we have. Few plants develop root systems equal to those of this plant. Judge Quarton said so when pointing in *Farm and Fireside* to the growth of sweet clover on his farm. But sometimes we need to see for ourselves. Grantham, of Delaware, has made a comparison. He says:

"A year ago sweet clover, alfalfa, and mammoth red clover were sown side by side in oats. Owing to the lateness of the season, and wet condition of the ground, the oats were not seeded until April. When the oats were harvested the sweet clover had made a growth of 18 inches, the alfalfa 10 inches,

and the mammoth red clover about 5 inches. On August 1 a number of plants of each of the legumes was dug up, care being taken to remove the roots with as little damage as possible. The dry, hard condition of the soil prevented the removal of the roots of the alfalfa and sweet clover to their full length. The sweet-clover roots were fully twice the length and size of the alfalfa roots. The root development of sweet clover during a period of ninety days, when grown with a nurse crop of oats, indicates the value of the plant as a subsoiler and its bearing on soil improvement.

The soil on which the legumes were grown is a clay loam, and produced 50 bushels of oats per acre this year."

Besides this evidence in favor of sweet clover we must remember that the sweet-clover roots, quick in growth as they are, are likewise quick to rot. Consequently they do not make the trouble that alfalfa roots do at plowing time, and some say they equal alfalfa roots as soil-enrichers. And yet sweet clover is not esteemed as is alfalfa. Why? Perhaps we have used neither of them as much as we should, and so do not fully appreciate either of these crops.

TEMPERANCE

"NATION WIDE" PROHIBITION NOT SO "DISASTROUS" AFTER ALL.

The following, which we copy from the *Jacksonville Times-Union* of Nov. 19, comes pretty near being the most convincing argument for absolute prohibition I ever came across. Can the Ohio Anti-saloon League find anything better to give the people in the present crusade than this? Just think of cutting off a "revenue" of *five hundred millions at one stroke, and in one day*, and instead of "disaster" *great good* came at once. Read the following:

COMPLETE PROHIBITION IN EFFECT THROUGHOUT THE RUSSIAN EMPIRE.

PETROGRAD, Nov. 18.—Actual and complete prohibition is in force to-day throughout the entire Russian empire; and not a drop of vodka, whisky, brandy, gin, nor any other strong drink is obtainable from one end to the other of an area populated by 150,000,000 people, and comprising one-sixth of the habitable globe.

In every foot of Russian territory the word prohibition is taken literally. It does not mean a partially successful attempt to curtail liquor consumption, resulting in drinking in secret places, abuse of medical licenses, and general evasion and subterfuges. It does mean that a vast population who consumed \$1,000,000,000 worth of vodka a year; whose ordinary condition has been described by Russians themselves as ranging from a slight degree of stimulation upward, has been lifted almost in one day to sobriety.

On that day, when the mobilization began, policemen visited every public place where vodka is sold, locked up the supply of liquor, which is almost pure alcohol, and placed on the shop the imperial seal. Since the manufacture and sale of vodka is a government monopoly it is not difficult to enforce prohibition; and from the day the shops were closed drunkenness vanished.

The results already are seen in the peasantry. They are beginning to look like a different race. Marks of suffering, the pinched looks of illness and improper nourishment, have gone from their faces.

Their clothes are cleaner, and both men and women appear more neatly and better dressed. Homes of the poor, formerly destitute, now present something like order and thrift.

In Petrograd and Moscow the effect is fairly startling. On holidays inebriates always filled the police stations and often lay about in the streets. To-day unattended women may pass at night through portions of these cities where it formerly was dangerous for men. Minor crimes and misdemeanors have almost vanished.

This miracle virtually has been accomplished by one man. He is Michael D. Tchelisheff, a peasant by birth, originally a house painter by profession, then mayor of the city of Samara, and now a millionaire. Physically he is a giant, standing over six feet four inches. Although 55 years of age, his movements display the energy of youth; his eyes are animated, and his black hair is not tinged with gray.

In Petrograd Mr. Tchelisheff goes about clad in a blue blouse with a tasseled girdle and baggy black breeches tucked in heavy boots. He offers his visitors tea and fruit.

Speaking to-day to a representative of the Associated Press of what he had accomplished for sobriety in Russia, Mr. Tchelisheff said:

"I was reared in a small Russian village without schools. I picked up an education from old newspapers and stray books. One day I chanced upon a book which treated of alcohol. It stated that vodka was poison. I was so impressed, knowing that everybody drank vodka, that I asked the first physician I met if the statements were true. He said yes. I decided to take every opportunity to discover more about the use of vodka.

"At the end of the eighties there came famine in Russia followed by agrarian troubles. I saw a crowd of peasants demand from a landlord all the grain and foodstuffs in his granary, and I noted that every man who was taking part in this incident was a drinking man, while their abstemious fellow villagers had sufficient provisions in their own homes.

"At Samara I decided to do more than passively disapprove of vodka. At this time I was an alderman. Many tenants in my houses were working men. One night a drunken father in one of my houses killed his wife. Then I decided to fight vodka with all my strength.

"On supposition that the government was selling vodka for revenue, I calculated the revenue received from its consumption in Samara. I then introduced a bill in the city council providing that the city give this sum to the imperial treasury with the request that the sale of vodka be prohibited. This bill was passed. The money was offered to the government, but the government refused it.

"It dawned upon me that Russian bureaucracy did not want the people sober, because it was easier to rule autocratically a drunken mob than a sober people.

"That was seven years ago. Later I was chosen mayor of Samara, and subsequently elected to the duma on an anti-vodka platform. In the duma I proposed a bill permitting the inhabitants of any town to close the local vodka shops, and providing also that every bottle of vodka should bear a label with the word poison. At my request the wording of this label, in which the evils of vodka were set forth, was done by Leo Tolstoi. This bill passed the duma, but in the imperial council was amended and finally tabled.

"I then begged an audience of Emperor Nicholas. He received me with great kindness, and listened to me patiently. He was impressed with my recital that more revolutionary and social excesses were committed by drunkards than by any other class. He promised to speak to his minister of finance concerning the prohibition of vodka.

"Disappointed at the failure of my bill, I had abandoned my seat in the duma. It was evident the bureaucracy had obstructed the measure. Minister of Finance Kokovsoff regarded it as a dangerous innovation, depriving the government of 1,000,000,000 rubles (\$500,000,000) yearly.

"While I lobbied in Petrograd the emperor visited the country around Moscow and saw the havoc of vodka. He then dismissed Kokovsoff and appointed the present minister of finance, M. Bark.

"Mobilization precipitated the anti-vodka measure. The grand duke, remembering the disorganization due to drunkenness during the mobilization of 1904, ordered prohibition except in first-class clubs and restaurants. This order, enforced for one month, showed the Russian authorities the value of abstinence. In spite of the depression of war, the paralysis of business, and the closing of factories, the people felt no privation. Savings banks showed an increase in deposits. There was a boom in the sale of meats, groceries, clothing, dry goods, and house furnishings.

"The 30,000,000 rubles a day that had been paid for vodka were now being spent for necessities. The average working week increased from three and four days to six, the numerous holidays of the drinker having been eliminated. The working day also became longer, and the efficiency of the worker was perhaps doubled. Women and children who were seldom without marks showing the violence of husband and father, suddenly found themselves in an undreamed-of paradise. There were no blows, no rough treatment, and no insults. There was bread on the table, milk for the babies, and a fire in the kitchen.

"I decided to seize this occasion for a press campaign so far as this is possible in Russia. I organized delegations to present petitions to the proper authorities for prolonging this new sobriety for the duration of the war. This step found favor with his imperial majesty, and an order was issued to that effect. A similar campaign to remove the licenses from privileged restaurants and clubs was successful, and strong liquor was no longer of value anywhere in Russia.

"The second month of abstinence made the manifold advantages so clear to everybody that when we called upon his majesty to thank him for his recent

orders he promised that the vodka business of the government would be given up forever."

"NO MORE HEROIC REFORM MEASURE WAS EVER INTRODUCED BY ANY GOVERNMENT."

A friend in New York sent the following, but neglected to say what New York paper it comes from:

RUSSIA'S GREAT DRINK REFORM.

If the manufacture, sale, and consumption of whisky and all "hard" liquor were suddenly stopped in the United States—if the country's 2300 distilleries were put out of business by a stroke of the pen, and the Government's income of \$163,879,342 yearly from this source absolutely cut off—we should have a condition of things approximately resembling that brought about in Russia by the abolition of the vodka traffic. Yet even this parallel does not fully represent the revolution in Russia's drinking habits whereby 150,000,000 persons are affected at an annual cost to the Government of \$500,000,000 in revenue.

Doubtless no more heroic reform measure was ever introduced by any Government. It has remained for the absolute monarchy whose name is synonymous with oppression, but which yet anticipated our own free nation in liberating the serf, to give force to what is altogether the most remarkable temperance movement in the world's history.

Here is something more, from the *New York Times*:

But that Russia will profit in every way except that of immediate and direct income from such suppression of the use of vodka as is attained need not be seriously doubted. As always, too, the loss of revenue will be more than balanced by increased capacity to pay taxes, and possibly in the increased sobriety of its people the great empire will find more than compensation for its military expenditures of money and men.

France seems to be meditating like though less sweeping reforms, and hints of similar plunges into abstinence more or less nearly total are coming from other countries involved in the war. It all marks the world's new appreciation that alcohol and efficiency of any sort do not go together. This fact is now demonstrable by scientific tests of the most convincing sort, and it applies to war as well as to any other form of activity.

WHAT A QUART OF WHISKY MAY COST A COUNTY.

Since there has been such a talk about the loss of revenue if the saloons were ruled out, the following, clipped from the *New Republic*, may give us some light on the subject:

One of the citizens of Belmont County went to Bellaire some years ago and bought a quart of whisky, got drunk, and went out and killed a man. It cost the county about \$5000 to send the murderer to the penitentiary. The circuit court set aside the verdict, and sent the case back to the lower court for a new trial. It cost the county about \$6000 more to land the man behind the bars at Columbus.

Two years later Governor Harmon pardoned the murderer. The fellow went right back to Belmont County and bought another quart of whisky, got drunk, and killed another man. It cost the county \$5000 more to send him again to the penitentiary. Once more the circuit court reversed the decision and sent it back on error for a new trial. The defendant asked for a change of venue, and the case was heard in Jefferson County. It cost Belmont

County approximately \$8000 more to send the man finally to the penitentiary for life.

Of course, the distiller who made the whisky which, in turn, made the murderer, was not punished in any way. Neither was the saloonkeeper who sold the man the whisky.

The reader can see from this one incident how the profits on that bushel of corn went glimmering, and the other fourteen quarts are yet to be heard from.

However, it may be that one other quart out of that same bushel of corn has gotten in its work in Belmont County, for a few months ago the papers over there announced that the brother of the man who cost the county so much money as the result of drinking two quarts of whisky, purchased a quart of the same stuff, got drunk, and killed a man. Quite likely it will cost about the same amount by the time the case is finally disposed of.

In addition to all the expense, five families of the county have been deprived of their breadwinners, and the taxpayers of Belmont County are far from unanimous in a desire to turn any more of their corn into whisky.

There are two morals that might be deduced from the above transaction. First, the folly of selling whisky for beverage purposes; second, the folly of having an "easy" Governor who may be led to pardon a man out after he has, at an enormous cost, been landed behind the prison bars for the safety of the community. The Governor doubtless thought that, if he would give this prisoner his liberty, he would profit by his lessons; but he demonstrated to that neighborhood, and to the *whole wide world*, for that matter, that his place, and his only fit place, is behind prison walls. And then, again, it would indicate that his craze for whisky and murder runs in the family. I do not believe in the pardoning business, especially pardoning out *criminals* guilty of crimes like those pictured above.

GOOD NEWS FROM ARIZONA.

On Nov. 3 we voted Arizona dry by 3891 votes. But we had a hard fight to win, as the wets worked very hard, and they sent out a large amount of literature, judging by what I received myself through the mail. I am sorry to hear that the grand old State of Ohio went wet, as that is my home State, as I was born six miles east of Lima.

I had the privilege of visiting your factory at Medina in Sept., 1911, and will say I enjoyed the visit very much, as all the men seemed willing to answer any questions that I would ask them, and they all treated me very nicely.

Buckeye, Ariz., Nov. 17. ALBERT J. ROSS.

A "WET" EXPOSITION; SHOULD IT BE PATRONIZED?

Dear Mr. Root:—I am a stranger to you, but you are not to me. My father has taken your paper for twenty years, and my grandfather took it from its first publication. We like your paper very much, especially the Home talk.

As you seem interested in the temperance cause I thought a little "dry" talk would be of interest. San Francisco went wet six to one—a very nice place to invite our friends to the exposition next year, isn't it? I am telling my friends in the East not to come. A man who lived there said it is no uncommon thing to find dead bodies floating in San Francisco Bay.

I am a girl eighteen years old. My father keeps bees, and I am much interested in them; also in the prohibition cause.

Corning, Cal., Nov. 6.

CAROLINE HUBERT.

Thanks for your suggestion, my good friend; but are not the temperance people somewhat at fault that California went so *very wet*? It is reported the drys tried to pass a law making it a penitentiary offense to purchase and drink California wines in one's own home. We, even in this fight, must be "wise as serpents and harmless as doves."

CIGARETTES, AND TOBACCO IN GENERAL; WHAT THE OHIO FARMER SAYS ABOUT IT.

We take pleasure in clipping the following from the *Ohio Farmer* of a recent date.

Government statistics show that during the year 1913 the people of the United States consumed cigarettes to the number of 14,530,486,200. This was an increase of 2,186,633,708 over the previous "banner year." Think of it! This is an average of 39,000,000 cigarettes each day, and the total value of all of these coffin-nails was \$72,781,626. One authority has estimated that it must have been necessary for 1500 boys to fall victims to the devastating habit each day, in order to keep up this terrific demand. It is also observed by sociological workers and students of the general question that the taste for liquor in a mild form is inspired by constant smoking, and the habit is thus responsible for many of the most serious woes of society. Dr. Dennis, of the medical school of Cornell University, states that "the tendency to beer-drinking is greatly strengthened by cigarette-smoking, because this habit becomes almost constant, causing a dryness of the throat and fauces, and hence irritating the throat." Another effect of cigarette smoking, we are told, is that it lands more boys in the police and juvenile courts than all other habits combined. One city magistrate testifies that out of 300 boys brought before him, charged with various crimes, 295 were cigarette-smokers. While it may not be true to say that every boy who smokes cigarettes acquires criminal tendencies, it is true, beyond question, that every boy or immature man who indulges in the habit to any extent suffers certain physical impairments that lessen his value as a worker, either with his muscle or his brain; and he is placing a serious obstacle in the way of his success by continuing the habit. The records of Harvard University have been cited to the effect that while over 83 per cent of the students use tobacco, for over 50 years no tobacco-user has stood at the head of his class. Smoking in any form does not do the smoker any real good, although it may soothe him and furnish him a certain amount of amusement and indulge a taste that has been acquired. It is less injurious to mature men than to young men who are just getting their development; and the boy who wishes to make the most of his career should refrain from tobacco.

May the Lord be praised that we have at least *one* agricultural paper that dares to come out like the above, not only against cigarettes but against tobacco in general, especially while it is true that so many men occupying prominent positions continue to set a bad example before the boys growing up all around them.

Cleanings in Bee Culture

The "New" Garden Magazine for 1915

Plans have been perfected for 1915 which will make the GARDEN MAGAZINE even more practical to the progressive amateur gardener than ever before. It may well be called the "new" GARDEN MAGAZINE. New plants, new flowers, new vegetables during 1915 will be brought before the notice of readers as quickly as the facts are available.

Special Features for 1915

Roberta of Roseberry Gardens

By Frances Duncan
The Author of "The Garden Doctor"

This is more than a mere romance hung around a garden. It is chock full of practical garden facts, dealing with the relationships of the nurseryman and the amateur who buys from a nursery.

The Garden Plan Every Month

The editors have secured the co-operation of competent authorities in garden design for the preparation of a series of what may be called typical layouts, one of which will be published in each number during the coming year, and will deal with plots varying in size from the city lot to several acres. Suggestive ideas will be given for the development of the property, shrubbery to be used, borders, etc.

In the Greenhouse

A series of timely, practical hints for the amateur who has a small greenhouse.

The Month's Reminder

Tells the amateur and beginner what to do and what pitfalls to avoid.

The War on Bugs

A new kind of spraying calendar which will cover in an entirely new way from a practical gardener's point of view, how

In their proper season numbers will be prepared with special reference to the particular needs of the moment, i. e., "Planting on Paper," "Seed Sowing," "Spring Planting," and other planting specials.

to combat with pests and diseases in all parts of the garden.

The Fruit Garden, The Vegetable Garden

These subjects are treated from the home point of view. There is an essential difference between growing fruit for market and for one's own table. The Garden Magazine point of view is the home exclusively.

Picture Feature

With the new cover of The Garden Magazine, opportunity is given for plant portraits, presenting them in full color. Watch the cover each month for plant portraits of real interest.

NO. 2

EDITORIALS

WHILE this issue is being read by our readers, the editor will be down in the Dismal Swamp looking after our bees. Possibly he will be disappointed in finding colonies have not made the progress we had hoped. What we find, however, will be given in our Feb. 1st issue.

"Many a Slip 'twixt the Cup and the Lip."

ONE or two letters from the vicinity of Norfolk, Va., indicate that the climate may prove to be somewhat disappointing to us, and that Hampton Roads Bay has been covered with ice at times. But where our bees are located is quite close to the ocean, some eight or nine miles from the coast, warmed by the Gulf Stream. Some of the colonies that we sent to Virginia were very weak, and we may lose some this winter. If so, our readers shall have the truth.

"The Development of the Apple from the Flower."

WE have for free distribution a folder entitled "The Development of the Apple from the Flower," by Prof. O. M. Osborne, Head of Horticultural Department, State Normal School, Lewiston, Idaho.

Under the sub-heads, "How the Honeybees Fertilize the Blossoms," "Why the Apple-blossom is Entirely Dependent on the Bee for its Fertilization," "How the Flowers and the Bees Co-operate for Each Other's Good," and "How Many Colonies of Bees are Needed for the Proper Development of an Orchard?" Prof. Osborne deals with every phase of the question, and shows conclusively that, without the bees, there will be no fruit, as the wind cannot pollinize the apple-blossoms.

We shall be glad to send these folders to individuals making application, for one cent to cover postage. Or we will send them for distribution postpaid in lots of a

dozen or more through societies if the name of the society with its secretary and president is sent us together with the number that can be used.

Small Pocket Electric Lamp for Looking in at the Entrances of Indoor-wintered Colonies

DID you ever try any thing of this sort? They are far better than a lantern, because they enable you to shoot the light clear up between the frames where the bees are clustered. Whether bees are wintering well or otherwise in the cellar, their condition can be easily observed with a pencil of light such as one can get from these little lamps.

There has recently been put on the market a very convenient electric lantern that makes use of a standard dry cell, such as one can buy at the telephone offices or any automobile garage for 25 cents. While it is much larger and more bulky, it does not have to be used on the flash-light principle. Indeed, the current can be turned on and left on, because it is big enough to stand the load. These cost complete about two dollars. We are using one of these in our bee-cellar with much satisfaction.

A Carload of Beekeepers from Chicago to the National Convention at Denver, February 16, 17, and 18

THE editor of GLEANINGS expects to be present at the Denver convention, where he hopes to have the pleasure of meeting his friends and patrons. An effort has been made to make up a carload of beekeepers at Chicago and go in a body. The following letter from Secretary Williams will explain:

The meeting of the National Beekeepers' Association will be in Denver this year, Feb. 16, 17, 18. Arrangements are being made for the Eastern delegates and visitors to meet in Chicago on Sunday evening, and leave about 10 P. M. on a special tourist sleeper, to arrive at Denver Tuesday morning at 7:00 in good time for the first session. This will

insure a splendid trip, and give opportunities to get acquainted and discuss matters while *en route*. The sleeper charges will be about \$3.00 in addition to the regular fare. Those intending to go from the south and west of Chicago will have the opportunity of joining the party if they will give me notice in time. All who are intending to go should write me and get full information, and thus insure ample accommodations.

Redkey, Ind.

GEO. W. WILLIAMS, Sec.

It is our intention to join that bunch of beekeepers.

Our Cover Picture

As mentioned on page 62 the picture on the cover shows a part of our Blakeslee yard in the Holtermann winter cases. We have twenty-five of these cases at this yard with four colonies in each and one case at the home yard, so there are one hundred and four colonies in all that we are wintering in this way.

For alighting-boards, we used a lot of old covers that were not worth much to form a runway from the ground up to the entrance. We would not recommend using a good cover in this way.

As shown in the photograph there are some dead bees in the snow about each entrance. This is true in every case, although before some of the entrances there were more bees. This brings up the question of whether it pays to shade the front of the hive or case to prevent the bright sun from luring the bees out on days when it is too cold for them to fly. While the matter has not been settled definitely the consensus of opinion seems to indicate that it is impossible to prevent a good many of the older bees at least from coming out in the sunshine and becoming chilled in the snow. Sometimes boards may be leaned up against the front to shade the entrance; but too often these serve to confuse the bees that do come out so that it is doubtful whether they are of much advantage. There are fewer bees in the snow about the entrances in the cases than there are in front of individual colonies separately packed.

"Buy More Cotton."

THIS is the slogan that has been going through the country to help out our friends and neighbors in the South who are loaded down with great quantities of cotton with no market for it. A great many people benevolently inclined have been buying it up, and this is certainly a move in the right direction. In this connection our friend H. G. Quirin, the queen-breeder of Bellevue, O., has got hold of an idea that may be worth developing. He writes:

The A. I. Root Co.:—We wish to ask whether you folks have ever tried cotton for cushions and winter packing for bees. We are thinking quite seriously of making sufficient cushions for all our outyards, and also our home yard, from cotton; but as we have never tried it, and know of no one who has tried it to any extent for a term of years, we thought it well to make inquiry in regard to its use.

Our brother put up five colonies last winter with about a pound cushion over each, and he speaks very highly of it; but last winter was rather mild, and the bees might have wintered without any cushion at all; and as one swallow does not make a summer we thought we would make further investigation in regard to the use of cotton as packing material for bees. We can get cotton by the bale for about 3 cts. per pound. Of course it is not of the very highest grade, but it would not be necessary to have the best. One hundred cotton cushions would be but half as bulky as that many chaff cushions. This would be quite an item; but one of their main advantage would be that they are perfectly clean. With chaff there is more or less dirt and dust sifting through the burlap.

Bellevue, Ohio, Dec. 21.

H. G. QUIRIN.

There will never be a better opportunity to lay in a stock of cotton-packed cushions for bees than right now. During the winter months beekeepers and their women-folks can make up a good supply. A thin cotton-packed cushion, if placed under a telescope cover, will make a wonderful difference in the amount of brood that one can rear in the spring during the early chilly days just after bees are taken out of the cellar. Our correspondent's suggestion is worth trying.

Not Paralysis but Poison, Perhaps

MAJOR SHALLARD's article, on page 995 of the December 15 issue, wherein he discusses the symptoms for what he calls the "disappearing disease," raises the question whether he hasn't had his bees poisoned. It may be that the bees were poisoned at their watering-place. Haven't we read in some place that our Australian friends sometimes poison a watering-place to get rid of the rabbit pest, fencing against stock with a coarse mesh, but not against rabbits—and bees? Or it may be there is some flower in that locality yielding a poisonous nectar. Why not, when we have the poison plants on the range, which, though appetizing to stock, are fatal to bees? Our own government has taken cognizance of this fact, and is trying to work out a system to protect the grazers on the forest reserve.

There is a disease known as paralysis, and this has come under observation in different localities; but we never knew bees to go to the field when once affected with ordinary bee paralysis. In all cases of paralysis we have seen, the bees got no further than the edge of the hive-stand, when they dropped on the ground and died within a foot of the entrance to the hive.

The name, "disappearing disease," is suggestive of some other cause than that suggested by Major Shallard.

The Montreal Bee Convention; the Proceedings in French

WE are indebted to the secretary of the Quebec Apicultural Society, Mr. O. A. Comiré, for a complete copy of the minutes of the deliberations of that association at its last meeting, which took place in Montreal Nov. 11 and 12. Only a lack of space prevents our giving it in full in our columns; but we will say it shows plainly the lively interest in apiculture on the part of our neighbors on the north.

Among many prominent beekeepers there we note Mr. C. P. Dadant, editor of the *American Bee Journal*, who gave a detailed account of his recent trip to Europe. As this convention was conducted in the French language it will be seen that Mr. Dadant had a great advantage, as that is his mother tongue.

Another man of prominence there was Mr. F. W. Sladen, Chief Entomologist of the Experimental Farm, Ottawa, who gave an interesting address on queen-rearing.

The Canadian Secretary of Agriculture was also present, who received the thanks of the society for his personal encouragement and practical assistance.

To further the work of the society the Canadian parliament has been requested to grant a little financial aid.

It is a source of pleasure to us to note the activity displayed by our Quebec bee-keeping brethren in their organic capacity. "One for all, all for one," seems to be their slogan.

Prof. H. A. Surface for Pennsylvania Secretary of Agriculture; the Right Man for the Place

WE are glad to announce, especially to our readers of the old Keystone State, that the friends of Prof. H. A. Surface are keenly interested in his appointment as Secretary of Agriculture. Prof. Surface now holds the position of Economic Zoologist; and those who know him best believe, and justly so, that there is not a man in the State nor in the United States, for that matter, who is better fitted and more able for the position. As a scientist he ranks among the first in the country, and he is a recognized authority on all nature-studies.

This particular appointment is the most important one to be made by Governor Brumbaugh, as it involves the agricultural interests of the State, and any thing that

promotes the interests of the agriculturists is for the welfare of every citizen.

Our readers should be keenly interested in securing Prof. Surface's appointment as Secretary of Agriculture, because he stands for the best interests of beekeepers. It was largely through his influence and untiring efforts two years ago that the State secured one of the best apiary-inspection laws in the United States. His appointment to the higher position would have a strong bearing on securing the much-needed funds for efficiently carrying on the inspection work. As president of the Pennsylvania State Beekeepers' Association he is in close touch with the interests of the beekeepers.

What is true of his relation to beekeeping is doubly true of his interest in fruit-growing and agriculture in general. A man who can take a poor worn-out piece of land worth \$30 or \$40 per acre and make it yield marvelous crops of fruit and field products so that it is worth more than ten times that much within a few years, deserves more than passing notice. Having charge of the orchard work of the State he is well known to orchardists through his untiring efforts in their behalf.

To place Prof. Surface in the high position of Secretary of Agriculture will mean to broaden his field of influence and usefulness. He is a man who has clearly proven his unselfish interest in the welfare of his fellow-citizens, and now this is their chance to reciprocate, at least in a measure. He is pre-eminently the right man for the place, and we trust that his thousands of friends will lose no time in getting back of his appointment.

Start a campaign in his behalf at once in your community. Get a letter off at once to Gov. Martin G. Brumbaugh, Philadelphia, Pa., urging the appointment of Prof. Surface as Secretary of Agriculture. Bring it before your grange and farmers' meetings also. Delay may mean loss to your own best interests.

The Kentucky State Beekeepers' Convention

ON Jan. 5 we had the pleasure of attending the meeting of the Kentucky State Beekeepers' Association, held in the Assembly room of the Experiment Station, Lexington. Professor H. Garman, Entomologist and Botanist of the Station and secretary of the association, was present, and a live wire he is. He has been with the university for 24 years, and during that time has done some valuable work for Kentucky. He is a friend of sweet clover, and believes it has a great future in his State.

The meeting was called to order at ten o'clock, when we listened to an address by President Henry S. Barker, formerly judge of the Supreme Court of Kentucky. While he has not, perhaps, had the training that a college president is usually supposed to have, he is a practical business man as well as a man of affairs; and we understand that the institution has prospered under his administration. In his address of welcome, he paid a glowing tribute to Kentucky, its resources, its products, and its future. He is greatly interested in every thing that pertains to making two blades of grass grow where only one grew before. He is a lover of the farm and of the soil, and of its possibilities; and last, but not least, he believes there is a great future for the honeybee in Kentucky now that sweet clover has taken such a foothold in that State. We shall refer to this further on.

Other addresses were given by the editor of GLEANINGS; by Attorney Richard P. Dietzman, of Louisville, on the laws relating to bees; by H. C. Clemons, of Boyd, Ky., on the Kentucky inspection law, and by C. F. Stiles on beekeeping in Mississippi. In the discussion that took place on the bee-inspection law of Kentucky, it appeared that the law was unconstitutional, and therefore it was without effect. While it is only a county law, an effort will be made to get it re-enacted. The beekeepers would much prefer to have a State-wide law, but the legislature absolutely will not provide the necessary appropriation for such a law. Foul brood is making some little headway in the State, and there is urgent need of protection. A committee was appointed to present some sort of bill for the next general assembly at its coming session, and it is hoped something can be done.

Wintering in Big Quadruple Winter Cases; Sealed Covers versus Absorbents

On page 2 of our last issue we gave a preliminary report of how the bees were wintering in the large quadruple winter cases. We have made another examination to-day, Jan. 9, going over a large number of colonies, and we find that, almost without exception, the bees under the glass covers are showing up a little nicer and brighter than those under wired screens with absorbing cushions above. In the case of the former the bees are well up toward the top. In the case of the latter they are clustered much closer, as if they were not as warm and comfortable as their neighbors in the other side of the case under glass

covers. While this showing is by no means conclusive, it makes us feel that, for the climate of Medina at least, a plain board laid on top of the brood-nest, with a bee-space under it, making a sort of semi-sealed cover, is better than a cushion held up by a Hill device or any thing that will make a bee-space under it. Glass covers or the board covers are not sealed; but they shut off the escape of moisture and hot air a little more, apparently, than the absorbing cushions that let both heat and moisture ascend up into them. Other colonies in the same yard are in single, double-walled, or old-style chaff hives. Bees in these do not look quite as well as those under glass in big winter cases. The difference, however, is not very great. We have also a number of colonies in single-walled hives alongside of the others. While these colonies are looking well, they show quite a sprinkling of dead bees in front of them. It would look at this time as if the shrinkage of the clusters, numerically considered, will be much greater in single-walled hives than where protection is afforded. This, of course, is to be expected. With reasonable protection it looks as if there would be good wintering this year.

The Wonderful Development of Sweet Clover in Kentucky; a Truth that is More Wonderful than Fiction

This plant is making great progress in Kentucky, and already sweet-clover seed, both yellow and white, is being shipped out of the State to all parts of this country in carlots. The amazing thing is that all the territory in three counties—Pendleton, Bracken, and Robertson—is devoted to the growing of sweet-clover pasturage and sweet-clover seed. In fact, we were reliably informed by E. E. Barton, of the Bokhara Seed Co., and by others also, that these counties grow almost nothing else. It is making rapid headway in other counties. So profitable has become the growing of this legume that it has crowded out all other crops, even tobacco. Now, tobacco (where it can be grown) is generally considered to be a profitable crop; but it appears that sweet clover on these Kentucky hills gives even larger returns to the farmer. Just suggest for a moment to any one of these farmers that the plant is a weed and you will find yourself bumping up against a bee's nest at once.

In a few years, comparatively, the growing of sweet clover will be one of the main agricultural industries of Kentucky. It is not only profitable for the growing of seed,

which brings good prices, but cattle that are sleek and fat are pastured on it during the entire season.

Sweet clover is a *continuous* bloomer. Beginning along about the first of June and July with the yellow, which is followed by the white, there is a continuous supply of nectar clear along till the fall. It goes without saying, that the three counties mentioned—Pendleton, Bracken, and Robertson—where it is grown almost exclusively, make a fine bee country. Indeed, we were informed that in one of the counties there are 4000 colonies.

A good part of Kentucky is rolling land, consisting of knobs, hills, and some mountainous country. The limestone rock sticks out of the sides of the hills.

It took the farmers of the State some little time to realize that there is money in sweet clover. But they are not so slow to catch on now; and at the present rate of increase Kentucky will produce more sweet-clover honey than any other State in the Union; and that will be going some, because some of the western States are now producing a large amount of it—carloads and carloads of it. Kentucky will also be a land that will produce large quantities of meat and sole leather—two commodities to-day that are commanding high prices.

Another thing sweet clover is doing is to renovate the soil on some of those farms. Professor Garman, the Botanist and Entomologist, was somewhat skeptical about this at first. He was also rather unfavorably impressed because he could not get his stock to take hold of it; but he says there is no use in denying that the cattle where they are educated to it were thriving on it, and that it is proving to be a great soil-restorer.

We learned of one particular instance of one farmer whose land gradually went down until he reached almost the starvation point. He found there was a tendency on the part of sweet clover to grow on the land; but as he was opposed to the "weed" he kept it well cut down. He was disgusted, and finally moved to town, leaving the farm to take care of itself. In the mean time sweet clover overran the whole place. The neighbors began to tell him that his farm would grow crops as before if he would come back and cultivate it. He did so, and began to gather the seed from the "weed," as it had a market value. At the same time he began to grow other crops, for the farm was completely restored. That farmer is now one of the most enthusiastic sweet-clover men in Kentucky. This is only one of other instances of a like nature.

Such a man as Alva Agee, of the *National*

Stockman, and one of the professors in the experiment station of Pennsylvania, and Mr. F. E. Dawley, of the experiment station in New York, both speak very highly of the plant as a soil-restorer. Yet in spite of all this testimony—in spite of the fact that it is being grown, hundreds and hundreds of acres of it in Kansas and Oklahoma and many other of the western States, we find that some old fogies and even one college professor still call sweet clover a noxious weed of no earthly use to any man. But there is no argument so strong as facts. When some of those who formerly opposed sweet clover are now finding that this same plant is pouring money into their pockets they may well "stop, look, and listen," for to see is to be convinced.

So delighted were we with what we learned about sweet clover in Kentucky that we have decided to drive down into the districts next summer to see the hogs and cattle and bees that are living and thriving on this so-called "noxious weed."

We omitted to state that the seed-gathering and nectar-gathering on the part of the bees continues throughout the season. The dry seed-pods and stalks are gathered while the bees are at work on the blossoms above. In the mean time the cattle and pigs run promiscuously through this luxuriant growth, furnishing milk, butter, and meat as well as sole leather. "Butter and honey shall he eat," and the three counties of Pendleton, Bracken, and Robertson are furnishing both, and then some. The truth is more wonderful than fiction; and when we go down into that country next summer we shall be equipped with cameras, and let the pictures speak for themselves.

The Behavior of a Cluster of Bees in Midwinter, as Observed by the Editor of Gleanings at Medina

IN our issue for Nov. 15, page 789, we gave a review of Bulletin 93 on the subject of the temperature of the honey-cluster in winter, by Dr. E. F. Phillips and Mr. Geo. S. Demuth. In this it was shown that a cluster of bees in winter is not necessarily as still as death, although examination over the top of the frames might give that impression. It was also shown that the cluster has the power, when the outside temperature drops to a certain limit, to raise the temperature inside by means of bodily exercise, consisting of active movements on the part of the bees tugging at each other, shaking their bodies, and actually fanning with their wings. These showings were decidedly interesting—so much so that we

decided to construct a special hive with glass sides, put bees therein, and see for ourselves. We accordingly constructed a double-walled hive with packing at front and rear, and at the top, and space in the hive proper to receive one comb filled with stores, and wide enough to take in a fair cluster of bees. Indeed, there was room enough to take in two frames; but in order that we might see the bees on both sides we put in only one comb. The sides of this hive to permit observation could not of course be packed and paneled with double-walled wood sides. We used instead three thicknesses of glass spaced $\frac{3}{8}$ inch apart, making two dead-air spaces. Dr. Phillips and Mr. Demuth, in their experiments, used only two thicknesses and one air space; but we decided to go a little further as our own climate is relatively colder.

The hive was duly installed and set on a support outdoors about ten inches in front of a window of the editorial sanctum.

Every thing was going nicely until we had a day of bright sunshine; and before we knew it old Sol shining through the glass sides made the interior of our experimental hive about like a hot-house. The cluster was immediately broken, of course, and the bees busied themselves by sliding up and down the glass inside of the hive, trying to escape, and some flew out at the entrance, notwithstanding the outside temperature was down to freezing. We had not anticipated this hot-house possibility, so we immediately had some wooden panels made to cover the glass, one for each side. Temporarily some folds of burlap were thrown over the hive to shut out the sun.

Several days have elapsed, and the side next to the office window has the panel removed except during the hours when bright sunshine might warm up the hive through the glass. But in the few days we have had for observation we have so far observed exactly what Dr. Phillips and Mr. Demuth have reported. When the temperature in the hive drops down to below 40 the cluster will gradually draw up closer, and the outside ring of bees between the comb and glass will be very quiet, exhibiting no movement but breathing, as shown by a slight distension and contraction of the abdomen. When the temperature gets low enough outside of the cluster, the inside of the cluster will be honeycombed; that is to say there will be holes or cavities scattered all through. Inside of these little recesses there will be here and there a bee fanning with its wings. But the movement of the wings in the cluster is very different from the movement of the wings in front of the

entrance of the hive on a hot day to cause currents of air to pass in and out of the hive for ventilation. The wings in the cluster assume more of a tremulous movement, and apparently they move in such a way as not to cause any appreciable air-current.

Other bees will be engaged in pulling at each other. Still others will exhibit the same side movement of the bodies that we find in case of young bees that have just come home with their load of honey or pollen in summer. Throughout the inside of the cluster there will be a general movement, crawling in and out, even the queen participating in the "exercise." During all this time the outside ring of bees is perfectly motionless with their heads jammed in close together, apparently to shut out any escape of air.

We cannot quite understand *why* the outside bees should be sticking their heads into the cluster. If they breathed through the mouth, as do ordinary animals, we might surmise that it was for the purpose of giving their hot breath to the inside temperature of the cluster. But that is not the way bees breathe, but through little spiracles in the abdomen or thorax.

Another thing we cannot quite understand now is whether these movements as described produce the same effect on bees that they do on animals. In our case at least exercise stimulates the heart and soon a warm glow pervades the body. In view of the fact that the temperature of the cluster rises when this gymnastic work begins, it is to be presumed that the bees are not greatly different from their owners.

Later.—Dr. Phillips, to whom we sent a proof of the above, sends the following:

I scarcely need say that Mr. Demuth and I are delighted to have you confirm our statements, which may have seemed a little radical to those who had not seen what we did.

There are only one or two points to which I would call attention. In the paragraph concerning the position of the bees in the shell (see Bulletin No. 93, page 15, first five lines) we think that the close proximity of the thoraces and the interlacing of the thoracic hairs are important.

The next paragraph contains a misconception. Exercise in man produces warmth by the muscular activity, and the increased activity of the heart is the result of this muscular activity, not the cause of the warmth. The heat arises from the chemical changes in the muscles. This is true in both man and bees, while in man the heat-regulatory functions prevent a drop in temperature and bees have no such regulation.

Going back to the location of your thermometer, you are not measuring the temperature of the air immediately surrounding the bees. In Bulletin No. 93, page 15, top of page, see what we say concerning variation within the hive. Because of this variation your statement of the reaction when the temperature of the hive drops to below 40 degrees F. is somewhat misleading. The clustering comes, according to our observations, when the bees themselves and the air immediately surrounding them reaches 57 degrees F. The temperature at the bottom-board may be considerably lower.

E. F. PHILLIPS,
In Charge Bee Culture Observations.

Dr. C. C. Miller

STRAY STRAWS

Marengo, Ill.

THE chief thing in putting labels on glass, according to an item in *B. Vater*, is to brush the paste, not on the label, but on the glass.

INBREEDING, if continued for a time, is generally believed to result in deterioration. But Dr. Kramer

has shown that it merely emphasizes characteristics existing. Weak stock inbred will deteriorate, strong stock will not. According to that the great thing is to breed from the best without worrying about danger from inbreeding.

W. HERROD says, *British Bee Journal*, 405, that extracting-combs put away wet will not be attacked by bee-moth. "In the center of a pile of supers containing wet combs a brood-chamber full of dry combs was stored. These were entirely eaten up by wax-moths, which did not touch the ones immediately above or below." [This is interesting if true.—Ed.]

H. CHRISTENSEN asks if my Italians seal sections as white as hybrids did. I have not noted any difference. With almost any kind of bees I think there will be an occasional colony that will have watery sealing, also that will varnish the sealing with propolis; but when certain fall plants are yielding (and I'm not sure what they are), any and all colonies will do this varnishing.

THE annual consumption of an average colony is thus given in *Illustrierte Monats-blaetter*: Honey, 40 kilograms (88 lbs.); pollen, 20 kg. (44 lbs.); water, 20 qts. Others have estimated the honey as high as 200 pounds. [While 200 lbs. is higher than the average, 80 lbs. is undoubtedly low. Our experience in feeding to build up colonies seems to favor an intermediate figure. —Ed.]

DR. BRUENNICH reports in *Schweiz. Bztg.* a colony which had not swarmed in eleven years. The original queen, which he calls S (from which many non-swarmed queens were reared) lived nearly four years, the last ten months of her life having with her a successor, S'. S' lived more than four years; her successor, S'', being with her the last three months of her life. S'' reared a successor when a few days more than four years old. Excellent work was done by the colony all the while. No wonder the Swiss believe in breeding for longevity and toward non-swarmed.

"IF YOU use full sheets of foundation in sections it really pays to fasten it with melted wax an inch or so from the top on

each side, to prevent the tendency of the sheets swinging over when the bees cluster on one side, so that the comb is attached to the separator," p. 954. Formerly I had trouble that way, but not a single case for many a year. My remedy is much better than melted wax. Simply have strong colonies so the super will be crowded with bees, and then never will "the bees cluster on one side." [Your remedy is all right; but not all colonies will be up to the required strength. You would say, "Do not run them for comb honey, then." Perhaps you would be wise.—Ed.]

F. A. HANNEMANN, inventor of the zinc perforated queen-excluder, was born in Wartenberg, Germany, May 25, 1819. He came to Brazil, South America, in 1853, bringing with him two colonies of bees, which he increased the first summer to 28. He sold five of these, and increased the remaining 23 the next summer to 250. July 24, 1912, he died near Rio Pardo, Brazil. [The scheme of making holes big enough to let workers pass, and not queens or drones, is not one of the minor inventions in bee-dom. It is evident that Hannemann was not aware of the importance of his invention at the time.—Ed.]

PLEASE, Mr. Editor, don't say a V starter in a section is a satisfactory compromise, p. 954. It's false economy. The bees will fill out with drone-comb; and unless you use excluders the queen will go up and fill out your sections with drone-brood. [We grant that it is false economy to use V-shaped starters; also false economy to use narrow starters an inch deep at the top. But there are those who believe that full sheets of foundation cause too much midrib in the comb honey, and a tendency to revive the so-called manufactured comb-honey canard of years ago. Said a prominent honey-buyer two weeks ago, "I believe that all comb honey should be produced with narrow starters because full sheets make too much midrib in the honey." We ventured the suggestion that he could not tell, by eating, comb honey made on full sheets of foundation from that on narrow starters; but he thought he could. Personally we do not believe there is any appreciable difference in the midrib—certainly none that the public will recognize. But there are those who believe that it is unwise to use full sheets, for the reason stated, and hence our suggestion in the way of a compromise to use a V-shaped starter.—Ed.]

J. E. Crane

SIFTINGS

Middlebury, Vt.

That is certainly a "new discovery" or method of making chaff division-boards, fully described on pages 833, 834, Nov. 1, and well worthy of following.

Many colonies in this section have gone into winter quarters much lighter in bees than usual, and it will not be surprising if there is considerable loss in wintering. Such results are apt to follow a poor season as well as foretell a good one.

Wesley Foster, page 751, Oct. 1, says the Government bulletin on sweet clover should be in the hands of every person who wants to sow the seed. Quite right you are, my brother; and you might have added that it ought to be in the hands of every person whose land is adapted to its growth.

Our friend Arthur C. Miller, page 842, Nov. 1, quotes Allen Latham as saying that "good clean spit is the best thing for diluting royal jelly." This would seem to exclude those who use tobacco from this method of reducing royal jelly to a more fluid condition. I am sorry for them.

The experiments of the Department of Agriculture at Washington begin to throw a good deal of light on the subject of wintering. The discovery that has interested me most has been that, the lower the temperature outside the cluster, the warmer it is likely to be inside the cluster. This may account for the brood we often find in strong colonies in February, our coldest month.

Mr. Ames, in the Nov. 15th issue, gives a nicely illustrated article on wintering bees in a four-hive case with permanent bottom-board, somewhat after the plan of Holtermann. Those four-hive cases certainly look good, and I am sure they can do their part in carrying a colony through our cold winters; but I doubt if they are much better than single hives well packed. I made a case three years ago that would take twelve single-walled hives with their entrances at four points of the compass. They are well packed, and wintered well; but I fail to see that they do any better than in well-packed single hives.

Page 816, Oct. 15, in footnote to Mr. J. J. Wilder's article, you appear, Mr. Editor, to

take issue with him, contending that, if a ten-frame hive is the best size in one location, it must be in another. I honestly believe you are mistaken. Many of Mr. Wilder's yards are quite peculiar. In those places where the partridge pea is his chief source of surplus, the bees do not breed up into strong colonies for the reason that, while working on this source, they gather very little pollen, but they gather the nectar from glands from the base of the leaf-stalk. As a result, the amount of brood in most of these hives is quite limited, and colonies rather small. Of course a small brood-chamber will force such colonies into supers much better than a ten or twelve frame hive. I can well believe his statement that eight half-depth Langstroth frames are preferable to full-depth frames, as such would be ample for the brood, and it would force the bees to store most of their surplus above in the super. [Your points are well taken if the conditions are as you state.—Ed.]

There seems to be some mistake as to the amount of sugar syrup required to draw out a set of frames of foundation. The editor says that the foreman of the yards at Medina says, page 794, Oct. 15, that a colony drew out six combs of comb foundation one-half on one quart of sugar syrup, half and half, and that he thought they would complete the job on another quart. As a quart of syrup of this quality would weigh about 2 lbs. 10 oz., two quarts would contain 2 lbs. 10 oz. of sugar. If this was enough to produce six combs complete, then it would require 7 ounces per comb, or 3 lbs. 8 oz. of sugar to fill an eight-frame hive. Eight frames of drawn comb would weigh somewhere from a pound to a pound and a half of wax more than the foundation used to fill the frames. Some have thought it takes 25 lbs. of honey to produce a pound of wax; some have thought 20 lbs. Others have estimated that it takes from 10 to 16 lbs., while these Medina bees are able to produce a pound or a pound and a half of wax on 3½ lbs. of sugar. Well, I am not going to say they didn't do it, or that other bees can not do it while you are feeding that amount of sugar syrup. They will sometimes do it without any feeding at all; but I am a little skeptical about their doing it from the syrup fed them alone. Were they not getting more or less from the fields at the same time? [See what R. F. Holtermann has to say on this subject, p. 13, last issue.—Ed.]

BEEKEEPING IN CALIFORNIA

P. C. Chadwick, Redlands, Cal.

In the editorial columns there appeared a word of caution to would-be inventors of new hives and fixtures. The warning is doubtless timely; but all we now have we owe to the dreams of enthusiasts and the experiments of the dreamers. There are many things yet to come in the advancement of our industry, and it would be far better to disappoint than to discourage the good that comes from them.

If we are all successful in producing a crop of honey each year, we should fail from overproduction. Did you ever stop to consider what would happen if it were possible to pay every laborer in the United States ten dollars per day for thirty days to cease labor? The nation would starve to death. If we fail to get a crop, there is always some other place to fill the place we leave. If some other place fails we shall oftentimes be benefited by their failure. So the world goes. Production is based on ups and downs, in a give-and-take manner.

With the president of our State Association, as well as a majority of the executive board in the North, a new era has begun in our State Association. I am of the opinion it will result in a much more healthy condition of affairs. The fact that it will eliminate the petty politics which has been far too prevalent in the South is worthy of consideration. In Prof. Willis Lynch, Harry K. Hill, and J. G. Gilstrap we have a strong trio to govern the body. That Prof. Lynch as president will be the strongest and most efficient man for the place that we have had in recent years is well known. He is a scholar, gentleman, and a man of wide experience and travel, with a most pleasing personality and kindly disposition, and enjoys the confidence of all. M. H. Mendleson deserves thanks for his unrelenting fight for the North.

Wesley Foster speaks of the prohibition amendment carrying in Colorado. Well, it did not carry in California by a great many thousand. I hardly thought it would, on account of the tremendous influence the grape industry gave the liquor men in fighting the amendment. If it had been only a

question of killing the saloon alone it would have carried handsomely. Now the grapemen are fearing the result of another election in 1916, and are asking that the saloon men get out from behind them. I could stand it all pretty well as to that part; but when San Francisco voted three to one to defeat the red-light abatement law my shame for that city was complete. The loyal support of the rest of the State, however, overcame the result in San Francisco. San Diego voted three to one for the law, thanks to her good people. We are inviting the world to the two great fairs that are to be held at these cities. Our sons and daughters are invited to come to a city whose moral test has just been given. Shame, for the showing of San Francisco!

A movement has been started in San Francisco to divide the State into two parts—the southern part to include the counties of Santa Barbara, Ventura, Los Angeles, San Bernardino, Riverside, Orange, San Diego, and Imperial. A division has been talked of before in the South, due to the impression that the southern half of the State is paying an unjust proportion of the State tax. This time the movement has started in the North, due to great dissatisfaction on moral lines. The North (principally San Francisco) is angry because the southern half voted the red-light extinguisher amendment to the constitution on them, besides giving them an uncomfortable feeling on the prohibition question. In the South there is a feeling of as deep dissatisfaction over the showing of the North on these lines. So in common they have a feeling of desiring to eliminate each other. If the question should be submitted to a referendum I should not be the least surprised to see the separation come about. Should it come about it would leave almost the entire sage-producing section in what would be known as Southern California, while the only region producing alfalfa honey would be in Imperial County. The South would be, in my opinion, the gainer in this line, for practically all sage honey would come from the southern section, and would soon be known to be the only sage-producing State. With the grape industry eliminated there is no doubt that Southern California would be a dry State.

BEEKEEPING IN THE SOUTHWEST

Louis H. Scholl, New Braunfels, Texas.

Rain, rain, rain, and slush. This is a very general condition in Texas this December. Good fall and winter rains mean good honey crops the following year, however.

Inventory time was here at the close of last year. I wonder how many beekeepers have taken stock of their possessions; and how many are going to keep books during 1915, so that they may be enabled to "know where they are" any time during the year.

COMB HONEY ON HIVES IN WINTER.

The bad roads, caused by the long-continued rainy weather, have prevented hauling home a large part of our comb-honey crop. As a consequence, something over 35,000 pounds of choice white comb honey is still on the hives. As many as three and four supers are tiered up on many colonies. As we have not had much very cold weather, none of it has even begun to granulate; and as there is always a great deal of well-sealed comb honey that does not granulate at all during some winters, we hope that this may become true with all of it this year. As soon as the roads permit, most of the honey will be hauled in and put in "warm storage" however. This should prove an experiment of some value to the bulk-comb-honey producers who sometimes have difficulty in disposing of all their honey in the fall.

THAT BEE-BOTANY DEPARTMENT.

I am one, Mr. Editor, who would favor such a department in GLEANINGS. It is very essential that we be better acquainted with the flowers that yield the nectar for our honey crops. It is very important that we know the honey-yielders so that we can locate our bees properly and to the best advantage. Even outside of that, most of us do not live merely to make money out of every thing that we do; but for those of us who are after more knowledge of those things that have to do with our chosen pursuit, such a department could be made of considerable interest. I worked for years on the collection of Texas honey-yielding plants, and I believe I have about as large a private collection of the honey flora of one State as anybody. But I have not had the time nor have I been able to collect all the honey and pollen yielding plants that grow in Texas which help more or less in the yield of honey, pollen, or both. It is

interesting indeed to study nature's flowers, and doubly interesting if we consider the value attached to these flowers from an apicultural standpoint.

WHEN TO FEED THE BEES.

This question is asked very often indeed. There seems to be no end to it, in spite of the fact that it is so often discussed in the bee-journals. I have always been of the opinion that bees should be so managed as not to require feeding at all. However, there are times during a season when the colonies may become so short of stores that it becomes absolutely necessary to give them such assistance as they may need in order to tide them over. But outside of this I do not believe that it is as profitable to feed the colonies either in the fall or in the spring as it is to leave plenty of honey on the hives in the fall. We have found that colonies with plenty of stores in the hives during the winter and throughout the following spring always build up to rousing strength with very little attention, and are the colonies that gather the most honey during the honey-flows, especially the early flows. We have made it a practice, therefore, for many years, not to take honey from colonies too closely, but to leave really more honey than they may need. The result has been that we are enabled to get just so much better yields from our colonies than those beekeepers who believe in "robbing close," and then depending upon feeding sugar syrup in case the colonies need it. The trouble about such a plan is that too often the feeding is either neglected altogether, or not properly done, or not enough is fed for best results. Another objection that we have toward wholesale feeding is that it wears the bees out unnecessarily when they are needed the most. This is especially true in the spring, when every bee is worth several bees later in the season. Even in the fall it is a good plan to disturb the bees as little as possible. If we feed them, the wearing-out effect it has on the bees begins to show very early the following spring in that they die much earlier, and at a time when we ought to have them to aid in the early brood-rearing operations. The better way is to leave plenty of stores on the hives in the fall; and this will not only save feeding and the trouble connected with it, but will give the best results in the way of stronger colonies and larger honey-yields.

CONVERSATIONS WITH DOOLITTLE

At Borodino, New York.

QUESTIONS ON QUEEN-REARING.

A correspondent wishes me to answer these questions:

"If on the second day after a colony has been made queenless we take away all the brood and give the bees a frame containing only eggs from our best queen-breeder, why is it that quite a share of those eggs will disappear instead of all hatching into larvæ, as would have been the case had there been brood in all stages left?"

This is a question I have often tried to solve, but have never done so satisfactorily. Of course a part of the eggs are removed to give place to the larger queen-cells. I might as well say that I do not know why more than those necessary are removed unless the bees are thrown into an abnormal condition by manipulation. I have often noticed that eggs do vanish, as by magic, under certain conditions where a colony is made queenless, and especially from a nucleus under the strenuous circumstances of trying to see how many queens can be gotten from it in a season. Where we allow the young mated queen to stay in her nucleus till the first 100 or more eggs have hatched, before taking her away for shipping, every egg will be hatched; but if she is taken away when she has been laying only from twelve to thirty-six hours the larger part will disappear. And if this early withdrawal is continued the nucleus will become so weak after a month or two that it will succumb to robbers when a time of scarcity occurs. Who among the readers can give us further light?

He next asks, "What becomes of the eggs? Do the bees eat them?" I would not say that the bees always eat these missing eggs; for I am aware that where bees are drummed or shaken into a box so as to make a new colony of the drummed swarm, as we used to do in what was termed "artificial swarming," thirty to forty years ago, many eggs would be found on the board under the box three or four hours later if the queen was laying at her maximum at the time the artificial swarm was made. But I have repeatedly seen bees eating the eggs as they came from a queen when she was suddenly disturbed so that she drew her abdomen from the cell.

He now asks, "If the bees eat the eggs which are missing, are they used in the preparation of the royal jelly? If they are, would the eggs of a black or hybrid queen affect the coloring of the young queens reared from golden Italian larvæ?"

Because bees eat eggs, it does not necessarily follow that they enter into the food given the young queen larvæ, for, according to my observations, hundreds and thousands of eggs are eaten by the bees when they have no disposition to rear queens. In times of great scarcity the cells will be cleared of eggs by the thousand, and all ideas of brood-rearing given up; and if fears of the existence of the colony are entertained, even the larvæ will be eaten except those about to change to the pupa form, and these will be sucked dry in order that the existence of the colony may be maintained. And even if they did enter into the royal jelly they could only form so small a part of the whole that little or no chance for coloring could be given, even were there any grain of truth in the theory that food of any kind has aught to do with the color of the insect to which it is fed while the insect is in the larval form. From many years of observation I have failed to find that black or hybrid nurses, or eggs or larvæ from a dark queen, in a hive from which Italian queens are being reared, have any thing to do with the coloring of such queens.

The last question, "What is the shortest time after hatching, the weather being favorable, before the young queen leaves for fertilization?"

Five days after maturity is the least number I ever knew to elapse. But in natural swarming, or under most circumstances where the bees have their own way, and especially where the weather is favorable and the flow of nectar good, not one queen out of ten is allowed to emerge from its cell at maturity, for under such circumstances all but the first of the young queens are held by the bees in their cells till a decision is made as to future swarming. Hundreds are held from one to five days in their cells by the worker bees, after they would have gnawed off the capping to their cell, and come out, could they have had their own way. Queens are more often held in their cells in this way than is generally supposed. In one instance I opened a hive and found a young queen piping away vehemently. After looking the hive over I found a queen-cell with a queen in it which I had overlooked when cutting out cells previously. As there were plenty of bees in this hive I took the frame having this cell upon it, bees and all, and formed a nucleus. The queen made a successful flight the next day, and in two days more, or three days in all, she was laying worker eggs.

GENERAL CORRESPONDENCE

EIGHT-FOOT FENCES AROUND THE BEE-YARDS

BY R. F. HOLTERMANN

In "Siftings," page 883, Nov. 15, J. E. Crane does not agree with me upon the point of high-fence protection for bees. Now, I have met Mr. Crane at conventions in years gone by, and I have always valued his sound practical judgment. I read his department with interest, and find it instructive. There may be a condition, other than the fence, which brings about the result he mentions, or I have never knowingly had the combination of conditions he mentions. It is possible to find something an unqualified success for years, and then, owing to the introduction of another combination of conditions, find that in that particular instance it was a failure. Mr. Crane states, "I have known just such a yard hopelessly ruined in spring by such a fence. If the weather should be sunny, with cool north winds, such a yard will be many degrees warmer than outside." I reasoned that way before I tested the matter, but have never had the result he mentions.

Now let me say this: If bees are packed, there are many days when, so packed, they will not be influenced by the sun's warm rays, when, with less packing at the entrance, or with single-walled hives, they will be drawn out of the hive when the cold wind outside of the hive would be injurious to them. This is obvious, and is particularly true if the bees have had a cleansing flight. With the winter packing as I have described it, there is another advantage; and that is, that the first flight they have, unless there is an extraordinary rise of temperature, will not be at the same time with all the colonies. The stronger colonies, and those requiring a flight the most, will be those coming out first; and perhaps—in fact, quite often—those not requiring a flight will not fly at all the first day it is possible for them to fly. If a long time elapses between the time the well-wintering colonies might have had a flight, and when they can again fly, it may be an act of wisdom to disturb such colonies the first time when conditions are favorable. They will then winter better. This is particularly true of mid-winter flights under favorable conditions.

Next the side of the winter case from which the bees fly is not close to openings in the case in front, or the first to the right or left of it. This is on account of the way

the cases are placed, with the object of breaking the rows of flight.

Where hives are set out of the cellar, and placed in rows with the entrances all in the same direction in the row, the tendency—yes, general result—is for *all* the bees to fly about the same time, resulting in tremendous excitement, and liability of the bees drifting, by which we mean that the bees are attracted to the most populous colonies or to the ends of rows.

By having just a certain combination of circumstances it would seem possible to have the result Mr. Crane mentions; but I have not so far had this condition, and I have had more loss in years past from not having the protection now given. What I should like to ask Mr. Crane is, Was the fence about 8 ft. high? were the bees packed in outer cases? and were the cases so placed as to break the openings in the rows so as to have every second case each way without an opening for the bees to fly from?

Let me again say, I do not despise—in fact, I wish, if possible—a location with natural shelter; but I would sooner have the protection from spring cold winds a distance of 8 ft. from the ground than to have none; and when it comes to winter protection I consider such protection almost imperative.

TARTARIC ACID.

Mr. Crane is also inclined to find no use for tartaric acid. I find that, by using it, I can make the syrup thicker than if I do not use it. I am an advocate of late fall feeding in my section. With 100 colonies I like to feed about Oct. 15. The weather may be cool at that time; and if the syrup is made $2\frac{1}{4}$ parts sugar to one part water it may crystallize so that it is difficult for the bees to take it. This is found particularly true if an inverted perforated feeder is used, for the crystals tend to form at the bottom of the food. Where tartaric acid is used this crystallization does not readily take place. More than that, where this thick syrup is left in the jar I have known the jars to break from the process of crystallization inside. Why or how I cannot tell; but that it takes place I know to my cost. Where tartaric acid has been used the

crystals are an entirely different formation. They take *very* much longer to form, and they never break the jar.

On the ground of chemistry the advantage of tartaric acid can be explained. The bees storing the syrup rapidly cannot be expected to invert it as thoroughly as with nectar which they gather thin from the field, and then have to evaporate to a consistency

equal to the syrup made according to the above directions. A young man, quite closely related to me so far as practice is concerned, used to despise tartaric acid; but recently he experienced this crystallizing in cool weather, and remedied it by reheating the syrup in the feeders and adding tartaric acid.

Brantford, Canada.

MOVING BEES IN CAR LOTS

A New Arrangement of the Staging to Secure Greater Rigidity and Economy of Space

BY J. G. BROWN

Mr. Brown, recently from Colorado, is now one of our apiarists. He accompanied the second car of bees to the Dismal Swamp.—ED.

On page 547, July 15, 1914, appeared an illustration of a plan of car staging for moving bees by rail used by The A. I. Root Co. in shipping bees to and from Florida. But the severe strain to which the staging is subjected when holding a heavy load, and the bumps of the locomotive when switching, together with the excessive freight rates on bees, which in turn makes necessary the conserving of all possible room in the car, caused the devising of a more substantial and at the same time a more economical plan for future car cratings.

It will be noted by referring to the illustration mentioned above that the uprights bore the weight of all the tiers of hives above them, plus the weight of the staging. When the distance from the top of the upper tiers of hives to the railroad track is taken into

consideration, together with the heavy motion of the car, the reader will form some idea of the strain upon the uprights. Neither will he be surprised that a part of the staging gave way in the first car, and Mr. Marchant was compelled to stop cars in

FIG. 1.—Crating on platform ready to load.

FIG. 2.—One section in the car ready for the hives.

transit and rebuild the staging.

The original purpose was to arrange the hives so that any one of them could be removed in case the bees died on the trip; that the attendant might be placed at the least possible inconvenience if for any reason he wished to remove any colony. Experience showed that this was unnecessary. It wasted valuable space, for it is very bad to load a

FIG. 3.—Southern bound—first car.

large car to the minimum weight at best, so a plan had to be evolved that would reduce the waste space and at the same time increase the strength of the crating to be used. When necessary to take the bees south again, the form of crating shown in Fig. 1 was devised.

The reader will gain a fairly accurate idea of the simplicity of the crating by reference to the cuts. This crating was devised by G. H. Rea. It consists of five pieces 15 feet long, 1 x 3 inches; five pieces 2 x 4 x 33½ inches; five pieces 2 x 4 x 37½ inches. In nailing up, the cross-pieces were placed on the floor, beginning with one piece 2 x 4 x 37½ inches long set up on edge, then a piece 2 x 4 x 33½ inches long, and then alternating the pieces in this way until all the ten pieces were spaced, covering the

15 feet. It will be found the pieces were just 20 inches from center to center. Then one of the 1 x 3-inch boards was nailed on these cross-pieces just one inch from the ends. This allowed each cross-piece to project one inch to catch behind the upright strips nailed on the side of the car, as shown in Fig. 2. Another of the 15-foot pieces was nailed on the other end of the cross-pieces, allowing the long pieces to project 4 inches, the short ones coming flush with the edge of this board. The third 15-foot piece was spaced halfway between these two. The crating was then turned over and the remaining two boards nailed on the cross-pieces opposite the two outside boards already nailed on, and the crate was complete.

When the bees were loaded in the car,

FIG. 4.—Loading steamer on Norfolk dock. As shown, the hives were slid down the plank and easily transferred to the deck of the steamer.

FIG. 5.—Tug "Commodore" freighted with bees and supplies, standing off to let a log raft pass. George Rea on top, supplying water through the screens.

twenty uprights, 2x4's, long enough to reach within about one inch of the car roof, were used. These pieces were bolted to the crating with $\frac{3}{8}$ -inch bolts. These, as will be seen, were bolted to the ends of the long cross-pieces in the crating. When these uprights were bolted in place, short pieces 2x4 were cut long enough to reach across the alley between the sections. These were spiked to the floor. Similar braces were placed at the top of the uprights. The halves of the car were now braced with 2x4's across the opening at the door, both on the floor and up at the top, and the job was complete.

By using the present method one can load 320 colonies, or, if the weather is cold, 384 of the ten-frame size in a 36-foot car.

It will be seen that this method allows sufficient room to use a sprinkler over the tops of any of the hives because they require water, as they most surely will if the weather be even mod-

erately warm or the colonies be strong. It also allows an alley clear through the car from end to end and across the car from door to door, allowing room to carry water, trunk, suit-cases, etc.

When we loaded the car we had 16 in each tier in each section, or 64 in one tier in the whole car. We started on the floor of the car in one corner, setting the hives in pairs with their entrances toward the opposite end of the car, their backs tight up

FIG. 6.—All the comforts of home at the camp in the Dismal Swamp.

against the corner. The next pair of hives was set tight against the bottom of the first pair, etc., until 16 were placed. It will thus be seen that the arrangement allowed a space between the different pairs of hives for the free circulation of air.

When one tier was placed, a section of the crating was laid on top of the tier and crowded tight against the side of the car, which held it snugly in place. As mentioned before, the strips on the side of the car were so arranged that the ends of the 2 x 4's just caught behind them.

In warm weather this method of loading would be varied slightly by laying one sec-

tion of the crating on the floor and beginning loading on top of it so as to allow the free circulation of air under the bottom of the lower tier.

By this method the crating is simply carried out when the car is unloaded, and is ready for use again whenever it may be needed.

In cold weather, as explained before, the hives may be placed right on the floor of the car.

As a further precaution the bottoms are removed, and each tier takes nine pairs of hives, instead of eight. Of course, tops and bottoms are screened.

THE HOLTERMANN WINTER CASES USED AT MEDINA

BY H. H. ROOT

In spite of the widespread interest in cellar wintering we believe that the large quadruple winter cases have never been used so extensively as during this present winter. A large number of beekeepers are wintering their bees for the first time this year following the general plan of the multiple-hive winter case, or, as it is sometimes called, the tenement hive. We ourselves are wintering one hundred and four colonies in cases made according to the directions given by R. F. Holtermann on pages 664 to 668, September 1. See editorial, p. 2, Jan. 1.

From our own experience so far, and from a large number of reports which we have received, we are prepared to believe

that the winter case holding four colonies is the best solution of the wintering problem for localities where there are great extremes of heat and cold, especially in some of the more northern States, and in Canada, where the temperature goes below zero for a good many days at a time, and where there are high winds. Having said this we realize that cellar wintering will never be a thing of the past. The whole question depends on the cellar, on the locality, and last, but not least, on the man.

Good clear cypress costs in the neighborhood of \$34.00 a thousand. In making these cases, however, we selected a cheaper grade, costing about \$25.00 a thousand. However,

FIG. 1.—Each pair of hives moved out, and the winter-case floor set in place.

FIG. 2.—Two panels held in position to show the relation of the outside entrance to the hive entrance, and the "bridge" for keeping the packing material away from the entrance.

counting the lumber, paint, paper, and the labor, we found that the cases cost us very nearly \$5.00 apiece, or, in round numbers, about \$1.25 per hive. These figures do not include the packing material nor the labor of packing, etc.; therefore it may be seen that the winter case is not a cheap plan of wintering by any means, when the first cost is considered. But those who have wintered their bees thus for several seasons claim that the winter case is economical in the long run because of the fact that the colonies come through the winter in better condition than when wintered in any other way.

Assuming that the hives have been placed in groups of fours (two pairs back to back) it is necessary when ready to pack for winter to set each

pair of hives to one side temporarily and place the quadruple bottom of the case in place on a suitable foundation. In Figs. 1 and 2 we placed a single-hive bottom-board in position to show how it is supported, and how the entrance is bridged over to prevent the packing material from filling it up. A

FIG. 3.—The four hives in position, the regular covers removed, leaving only the super covers so that the hives may be close together.

FIG. 4.—An automatic screwdriver for putting in the screws at the corners of the case.

permanent bottom, such as the one described by A. C. Ames, page 889, Nov. 15, is a more convenient arrangement provided the same location will be used continuously year after year.

In Fig. 2 two of the sides are held in position temporarily to show how they telescope down over the edge of the floor.

In Fig. 3 some packing has been strewn over the floor between the supporting cleats and the four hives placed in position. We used baled shavings for packing, not because we consider shavings better than leaves as recommended by Mr. Holtermann, but because they were more convenient. The bale of shavings is shown just back of the four hives in the picture.

It is something of a problem to move twenty-five or fifty of these large cases after they are nailed up. We nailed up the sides, therefore, arranging the cleats so that every thing would fit together properly, and then moved the whole outfit in the flat to the Blakeslee yard, where we intended to use them. Screw-holes had been drilled in the proper places, and it was but a short job to screw the corners together with an automatic screwdriver, as shown in Fig. 4. It would have taken less time to nail the corners; but since it would be more difficult to take them apart in case we should have to

transfer them to some other yard in the future we decided to use the screws.

Fig. 5 shows the case set down over the four hives and the shavings added. We remove the regular covers, using the super covers only so that the hives may be placed close together, as shown in Fig. 3.

Fig. 6 shows one of these cases in which we are wintering four colonies at the home yard just after we had finished packing it.

The cover picture for this issue shows one of the cases out at the Blakeslee yard after a month of snow and ice. We have two bee-cellars which we consider almost ideal; but somehow we have a more comfortable feeling when we think of the bees in these snug winter cases than we have when we go into either one of the cellars. Perhaps it is because we imagine that the bees, if given their choice, would ask for their hollow tree and the privilege of flying whenever the weather is suitable. A winter case is probably the nearest approach to the hollow tree practicable for the modern beekeeper. So far as we know, the winter cases give such protection that the clusters maintain nearly the same position regardless of the temperature outside.

FIG. 5.—The case set down over the hives, and the packing material put in.

REPORT OF THE CHICAGO NORTHWESTERN CONVENTION

Prices, Production, and Transportation Considered

BY J. L. GRAFF

One of the delegates to the Chicago Northwestern Beekeeping Association meeting held in Chicago December 17 and 18, struck a responsive chord when, in a modest talk, he advocated a more altruistic feeling among the men who engage in the production of honey. For several years the doctors, members of the American Medical Association, have been employing a lecturer to travel among the physicians of the nation to teach this kind of feeling for one another, and it is said to have had the most desirable effect. This beekeeper thought it bad policy to go about knocking one another, knocking the honey and the prices of others—better go around helping one another for the good of all. This little advice followed a hot discussion about prices, whether a beekeeper should put on a fancy price to indicate that the goods were of high quality, or whether the price should be kept within the reach of the average consumer. One apiarist held to the opinion that, if he established a high price, the buyer would form the impression that he was offered top-notch goods. The man who was satisfied to charge a less price resented the implication that his honey was not as good. From time immemorial these discussions have warmed up beekeepers' meetings, and doubtless this is the reason the modest man in the back row essayed to mix in a little leaven.

Nearly fifty men attended the meeting. They hailed from farms and homes within the Illinois, Indiana, and Wisconsin district close to Chicago. There was a considerable amount of woe mixed in with the natural jollity of the beekeepers, for nearly all of them told of a shortage of crop from the last honey-flow. An Iowa man got from his bees about 40 lbs. to the colony; a northern Wisconsin man had taken 80; a northern Indianan, 40; a northern Illinoisan, 40; a central Illinoisan had no surplus at all; a Lake County, Indiana, keeper, got 40; a Chicagoan 45; another Chicagoan

75; a western Illinois man 30. The largest production was reported by a member from central Wisconsin, 115 lbs.; and another Badger said that he had a surplus of 85 lbs.

FIG. 6.—The cover on, and the job complete. The cover is roofed with a good quality of paper, and painted.

The other productions ran from forty down as low as twenty, and four said they had no surplus at all, and were heavy sugar-buyers in preparation for the winter months. The drouth of the late summer and fall months curtailing bloom was given as the cause of the light crop.

One of the most interesting talks of the convention was made by H. C. Ahlers, West Bend, Wis., who related some of his experiences in shipping his apiaries to vast Spanish-needle beds on the bottoms adjoining the Illinois and the Mississippi rivers. The cost of freighting from his home to Louisiana was \$170 a car one way—500 colonies to the car. This did not include his own transportation traveling with the car; and this fact brought up the question as to the alleged unreasonableness in carrying a stockman free with his stock and charging a beeman for the privilege of riding with and caring for his bees *en route*. Mr. Ahlers told how he managed to secure the colonies in the car so that they will not be jolted out of place. He fastens stanchions in the car, leaving space to walk from one end of the car to the other. The space at the doors is left vacant for his own occupancy, but the hives are tiered up as high as the height of the car will permit. Plank nailed on lengthwise and crosswise at the doors are fastened

to the stanchions and wedged tight, so that none of the hives are jolted about. He carries 40 sixty-pound cans of water, and gives this to the bees by pouring it on the screens at the top of the hives, the passageway allowing him access for such purpose. An ordinary stock-car is used.

Another apiarist told of using refrigerator cars, by which plan an even temperature was preserved *en route*.

E. G. Bacon, of Wisconsin, talked on the subject of educating the people to eat honey. It isn't enough to say to a family, "Eat honey." The thing to do is to tell them why they should do so, to demonstrate the manifold points of utility, and to point out opportunities to substitute honey for sugar. The beekeepers should start a propaganda of this nature, but it cannot be done unless the money is first raised. One of the speakers said that if every beekeeper would contribute the price of half a pound of honey much could be raised for such an educational campaign. People of other countries, notably Germany, consume vast quantities of honey, and at a cost much in excess of prices in this country.

The question was brought up as to why the big bakeries are making use of less honey. It was stated that a big concern that formerly made use of 125 carloads is now using but fifteen. A South Water Street commission man said that the honey-sweetened cakes are less in favor.

E. S. Miller, Valparaiso, demonstrated the use of a bee-cellar in wintering bees. The proper temperature in this cellar is evenly maintained by the use of a sub-earth vitrified eight-inch air-duct, starting fifty feet away from the building at the earth surface, and opening on the bottom of the cellar. The cellar, 18 x 24 x 7, has a story above it, and then an attic. An upright flue

extends from the bottom of the cellar through the roof, and a stove on the second floor heats the air sufficiently to keep up a circulation. The basement is of concrete. In this cellar Mr. Miller winters from 100 to 200 colonies with good results.

It is claimed that only a very small percentage of beekeepers belong to associations, although memberships are increasing; and considering the crops of the last season, and the territory covered by the Chicago Northwestern, this convention was a good one, chock full of real live interest.

A feature of the convention not printed in the program proved to be the most unexpected but none the less interesting.

During the forenoon session of the first day a man who looked like a prosperous farmer, about sixty years old, and who had participated in some of the discussions, was seen to move toward a closed piano in the corner of the room during a recess. Above the buzz of conversation was heard a lively tune, and the player was discovered to be the farmer beekeeper. He played none of the rag-time stuff of the present day, but the melodies which most people love. The name of the man at the piano is John Kleine, and his home is in Mendota, Illinois. He said that he had been playing the piano since he was a boy. He has a son and daughter, both musicians. The windows of his music-room open out into his beeyard; and when asked if he played for the bees as well as for himself and his family he said he did.

No one at the convention volunteered any remarks as to the effect of music on bees. The subject wasn't discussed; but we know of several instances in which dairywomen and dairymen believe in the efficacy of music for the cows at milking time.

Chicago, Ill.

A FINE FLORIDA BEE PASTURE

BY F. M. BALDWIN

A city engineer has little time for any thing but his regular task; but the close of the second week in October gave me a few hours off, and I took advantage of it to cross the river and hurry to the country south of Bradentown to see the bees that I had recently obtained from J. B. Notestein. I had bought four hives of him; and, acting on the advice of that expert beekeeper, C. H. Clute, I had divided three of them, one being too weak for successful division. My route took me just east of the creek where A. I. Root's ducks met the alligator. Just

a little south of his chicken-yard was a great patch of gold gemming the landscape. A little further my eyes were gladdened by two more. Then there were others; and east of Bro. Ault's home yard was a great field of the cloth of gold. The wild sunflower was coming into full bloom. No nectar yet—but, ah the promise!

An examination of the hives revealed lots of brood and much new honey, evidently from Spanish needle, of which there were quantities on every side. To add to my expectations, goldenrod was beginning to

FIG. 1.—Colonies strong in honey above and below, and only six weeks on the stands, during which time each colony was divided twice.

show color, and that is usually followed by sweet myrtle, from which enough stores are gathered to carry us through to orange bloom in February and March. On my way back to Palmetto I plucked a big bunch of wild sunflower to prove to Mr. Clute that things were going well with my bees. But he had been further afield than I, and my tale was but a tame one to the one he could tell.

THE BIG SAWGRASS.

In the vernacular of South Florida, "a sawgrass" is a flat that is under water most of the year, and on which grows a wild grass with a fine saw edge. It is what covers most of the Everglades, and its presence means first-class land, rich and black. We have many sawgrasses in Manatee County—some of them covering hundreds of acres. The tract to which the title "The Big Sawgrass" is applied is about a mile north of Erie station, on the Seaboard R. R. It covers about a thousand acres. Too wet as a rule for fall and winter crops, it is given over to tomatoes in the early spring, and brings bountiful crops of them. The rest of the year it is covered with smartweed, thoroughwort, and wild sunflower. For the sake of brevity I shall call the last-named flower W. S. F., and the tract of land as the B. S. G. The last week in August Mr. H. L. Christopher, discouraged with the poor yield he was getting at Terra Ceia Junction, moved his bees to a live-oak hammock on the west side of the B. S. G. As Mr. Clute is the adviser of everybody in this section who works with bees, Mr. Christopher had taken him out that day to see what wonderful luck he was having, and to

get his suggestion as to future manipulations. The tale he had to tell so far exceeded mine that I soon stopped talking and took to listening. Having first seen the light in that great State on the west bank of the Father of Waters that takes its name from the mighty Missouri, I had to be shown, and we agreed to run up to Erie Monday afternoon and look the B. S. G. over.

About 3 P. M. the train left us at the little flag station, and we walked north across the prairie through the

saw palmetto. A mile and a half of that kind of thing grows monotonous, and we were not sorry to rest and look at the flight of booming bees. The 20-weak colonies had been divided and were now fifty strong ones. Hives from which colonies had twice been started were carrying a super, and the super was full of capped honey. Every hive of the fifty was heavy with stores, and seemed to be begging for combs or foundation—any old thing in which to place nectar. To us it looked almost like a crime that the beekeeper was not right there vigorously running an extractor. It was more room or a bad case of swarming, and that right then. Before he would let me snap a picture, Mr. Clute insisted that we take the liberty of sampling smartweed honey, which he said was of the best. A taste was all that was needed to convince me that it was A No. 1 white, of fine flavor, and should command a top price in any market. The picture was then taken, and we started to explore the B. S. G. *Explore* is the correct term. It was a wilderness of weeds, many of them far above our heads, and only by hard work could we make any headway through the tangle of heavy growth. The bees sailed over it with ease, carrying loads of sweets. But we could scarcely penetrate its dense jungle of grass and flowers. We knew that we were near the big drainage canal that had been completed within the last year, and thought that if we could get to it we could go east along its left bank to the head of the ditch. The steam-shovels had dropped the earth and marl fifteen feet from its banks, and we planned to travel along this spoilbank. But W. S. F. had

FIG. 2.—The big drainage canal in Florida, showing how the wild flowers crowd the banks.

complete possession of the spoilbank also. We could not make progress along it, and we dropped down into the ditch and walked at the water's edge on a slippery, sloping incline set at an angle of 45 degrees.

After what seemed an hour we came to a bridge and a road which led toward the railway. We climbed out of the ditch into the road, catching a snap-shot by the way. Everywhere there were vast stretches of nectar-bearing plants. In a comparatively open place Mr. Clute gathered a bunch of boneset and held it up while he posed beside a clump of W. S. F. that towered far above his head. The boneset and the smartweed had been in flower for more than six weeks. They looked as if they were taking a fresh start with a second crop; and the W. S. F. that gemmed with gold this rich region was just coming into its own. There were acres upon acres of honey—enough to keep a thousand colonies busy for months, and only fifty colonies at one corner. What a wealth of sweetness going to waste!

As we walked we discussed the wisdom of bringing bees to save a little of this vast store. Ours were doing well where they were. Spanish needle and goldenrod would give them pasture for a while, then would come sweet myrtle, on which they always grow rich. To move meant time, trouble, and expense. We thought we might as well let well enough alone.

Then we talked of the future. What about 1915? Should we keep the bees on their present stands until after the orange and palmetto flow, then get them in June to the B. S. G. for a summer and fall killing? The old beekeepers, like Poppleton, claim that

there is no honey-flow on this peninsula in August. But we believe we can show them that the last word has not yet been said about Florida possibilities. The longer one stays in this great State the more he finds what it can do. Mr. Christopher had a summer flow, and he was at least a month late getting there as we figure it. There are other sawgrasses, and they should be as promising as this.

INTRODUCING BY SMEARING THE QUEEN WITH HONEY.

Mr. Clute had a fine year—more than 30,000 pounds and 100 per cent increase. If he carries out the project that we discussed he should be able to show three times as good a year in the one that is coming. Like all old hands with the bees, he has a store of practical knowledge that is very valuable to the novice. On one occasion, when I had a high-priced queen to introduce, he said, "Let the smoke method go. Put her in half a cup of honey. Don't be afraid to push her 'way down into it with your fingers. Smear her all over. The bees will lick her clean. Get her covered deep, and pour her and the honey into the top of the brood-chamber." My heart sank when I saw her apparently drowned in the honey smothered in sweetness. But the deed was done, and I could think of no way to get the sticky stuff from her body and wings. The bees would have to do it or she would be hopelessly smothered. So into the hive I poured her. When I opened the hive after several days I found that she had been accepted, and was doing all that one could desire of the mother of the colony. Not long after, I repeated the operation. This

FIG. 3.—Mr. C. H. Clute standing in smartweed and boneset, looking up at the wild sunflower.

time it was a virgin, and she was laying when next the hive was examined. Mr. Clute claims to have used this method for years without a single failure. It is easy; and, if safe, just what the fraternity has

been looking for. Has anybody had an experience that has given a different result? Will some venturesome spirit please try it and report? It will probably prove simple, safe, and successful.

CALIFORNIA CONVENTION REPORT

BY P. C. CHADWICK

The California State Beekeepers' Association convention was held as scheduled, Dec. 16 and 17, at the Y. M. C. A., Los Angeles. The attendance was not up to the usual, which may be accounted for to some extent by the fact that rain and threatening weather continued throughout the two days.

The first session was called to order by the president, Mr. Farree, who gave what he called his message to the convention. Prof. Cook being present, but unable to attend the following day, was given preference on the program. His talk was both interesting and instructive, and he was given a vote of thanks for his remarks. He spoke briefly of the beekeeper and the horticulturist, after which he gave a long and interesting talk on honey as a food—its relation to the physical economy. Reviewing the food contents, especially sugar, in various food staples, and comparing them to honey was the main feature of the address. It was the first time the writer had had an opportunity to hear Prof. Cook lecture, and it was the

best discourse he has ever heard at State conventions. The association needs more men like him on the program each year. There are plenty of members who generalize in their thoughts; but to such men as Cook one must look for scientific facts.

Following Prof. Cook's address the discussion drifted into the weight of honey per gallon, cause of granulation, etc.

The afternoon session was called together by Delos Wood, with Harry K. Hill acting secretary. Few were present at the beginning of the session; but Mr. Wood announced "One o'clock is one o'clock so far as I have ever been able to learn."

The Los Angeles County inspector, Geo. G. De Sellen, gave a brief talk while members were getting to the hall. An interesting paper on marketing was read, discussion following, which drifted into the requirements of the net-weight law.

Prof. Cook again spoke, this time his subject being the proposed foul-brood law, in which he warned the members against

trying to force the bill through to the Governor as now proposed. His opinion was that the bill would be vetoed if the provision which gives the president and secretary of the association control of the board by legislating them as members of the board with a controlling power. There was some disagreement with Prof. Cook's opinion, one member even declaring that the bill could be forced over the Governor's head; but a very strong opinion prevailed that Hiram Johnson is still very much in evidence as Governor of the State, and any such policy could not be accomplished.

Mr. Wilson, the legal adviser of the association, spoke briefly on legal lines, after which he was given a vote of thanks, as he had spent considerable time and energy on association work without charging for his services.

The secretary's report was then read and adopted. A report was made by J. G. Gilstrap for Prof. Lynch, who is at the head of the northern division of the present exhibit committee, and who will have the responsibility for whatever exhibit is made at San Francisco. The exhibit as planned is to be of an instructive nature.

On Thursday, the 17th, Delos Wood, acting as chairman of the convention, called the meeting to order promptly on time, George Brown acting as secretary. Few members were on time at the call. The reports of the county inspectors were taken up. All inspectors reported some loss by disease, black brood being the most prevalent, with better conditions existing. The Los Angeles County inspector reported the number of colonies for his county, normally

60,000, had dwindled to 30,000. Great improvement had been made by requeening. It was his impression that, by the end of another season, they would be back to their normal numbers.

The open discussion as to the management of the journal, to which a number of the members had been assigned, was eliminated from the program, due to the fact that no good could be accomplished, and that it was sure to precipitate a very warm discussion, although there was no mention of these facts except a warning by L. B. Andrews. Mr. Andrews has a knack of sighting these rifles and avoiding them.

The election of officers resulted as follows: Willis Lynch, president, with A. B. Shaffner re-elected as secretary. Seven candidates were nominated for the executive board with but three to elect. Harry K. Hill and J. G. Gilstrap were almost unanimously elected on the first ballot, with George Brown and W. H. Allen tied. Mr. Allen won out on the second ballot by three votes. This puts the control of the association in the North.

An interesting report by J. Edgar Ross on his litigation over keeping bees in the city of Brawley was read. An unmistakable case of bee-poisoning was also reported. The raising of a legal fund for the protection of beekeepers was suggested by Mr. J. D. Bixby, which met a hearty response, and was immediately acted upon. The plan is to assess each member three cents per colony, if need be, one cent to be available at once, the other two upon call. The convention adjourned, with the understanding that it would probably be called in San Francisco next summer.

MORE ABOUT CAUCASIAN BEES

BY J. J. WILDER

In commenting on my previous article about Caucasian bees the editor states that they were great swarmers when under test; and from reports from other beekeepers they had experienced about the same thing; and, going further, in one of the articles, that on this trial the greatest season resulted with them in an almost complete honey failure on account of their high swarming impulse.

Mr. Benton, the importer of these bees, made the statement more than once in his writings that they swarm too frequently, but that they are good honey-gatherers. Once in a great while a beekeeper might experience the same thing the editor and a few others have experienced with these

bees; but even this might be said of what we call the best. This is surely not much ground upon which to condemn.

I have had years of experience with these bees in an extensive way, and have sent out several thousand of their queens to almost all parts of the United States. From the purchasers many reports have returned, and not one has reported the editor's experience. Yes, without a single exception, based on reports, every one is pleased with this stock.

I have had to discontinue the sales of these queens; and as I have none to offer I have no policy in this article except to bring out the facts about them as I have found them, and as others have reported.

We have found Caucasian bees almost

non-swarming under our methods of controlling them. We give them plenty of ventilation at the bottom of the hive, plenty of room at all times for the queen, and plenty of storing room, allowing no honey to be finished up next to the brood-nest during the height of the swarming season. The foundation is started and partly drawn out there, then raised, and another one given as long as they will draw out foundation. Then by our general method of frame manipulation we look over the brood-nest once a week during this time; and should any preparation for swarming be found we remove the queen-cells or divide them up, making two colonies out of one. The latter we do mostly, for we want the increase.

But there is only a very small part that ever attempts to swarm after the main honey-flow comes on, and the most of the increase is made on the first and second rounds in early spring. After the main honey-flow is on, only two or three natural swarms will issue from each apiary; and if we do not resort to frame manipulation the loss in bees is almost nothing.

What about these few natural swarms from these bees? They are not more than a mere double handful of bees, and not worth hiving. We have left off having the farmers living near our apiaries hive swarms for us, should they find any.

BUILDING UP.

This alone is almost a redeeming feature over the Italians. Artificial feeding is not necessary to bring this about if there are any outside resources obtainable.

It might be said that such rapid building up and great progress in this way, kept up throughout the season, might not always be in their favor. I have these bees in almost every kind of location in the South, and I never saw these colonies rise to such great pitch and go back. As a rule they maintain their strength, and store right on throughout the season. Of course progress may be slow at times when nectar is not so plentiful.

On the other hand, what do these great rousing colonies mean to the beekeeper who wants to spread his business, especially in the spring? Well, it means almost any amount of increase he wants, right at a time when it will be best to make it. In doing this I usually find two full-depth eight-frame hive-bodies full of brood, and very often a shallow extracting-super or two with some brood in them in addition. Very often I find as much as three bodies of brood, quite often four, sometimes five, and once in a great while six, with brood scattered through them. This may sound a little

"fishy," or the limit on extremes; but as I have a number of honest men working for me who know this to be a fact I am not afraid that I shall be branded as untruthful. The beekeeper cannot afford to ignore this fact; for it is a matter of great consideration by any beekeeper who is not pleased with the stock he has.

AS HONEY-GATHERERS.

I have mentioned this feature of these bees before in GLEANINGS, and it is not worth while to dwell on it, for the interested readers can refer back a few numbers and understand more fully. But under this head there is one more feature I wish to mention, and it is a redeeming one.

I have often been astonished at the progress these bees would make in storing in just a few days when the main flow came on heavily and suddenly, owing to moderating weather conditions. Up to May 10 this season it looked as if the crop from gallberry was going to be a failure. The bloom was far advanced; nothing appeared in the supers, and blooming would soon be past. But suddenly a great harvest took place at just the last moment as the blooming period was passing off. They just simply went wild over honey-gathering, and I never saw as great energy manifested in bees. They were simply ready for it in every way. We have few days of a great honey-flow in the South, and sometimes these are reduced to very few, owing to adverse weather conditions. The remainder of the season the flow is slow or weak, and a marvelous thing must take place during the short time it is at its best.

FINISHING THE ARTICLE.

There is nothing more fascinating than to remove from two to five supers of well-finished honey from each colony of Caucasians. These dark smutty-colored bees, when smoked, move down between the combs, in appearance like a dark mantle folding down from over the honey, which looks like frames of compacted snow, so beautifully white and evenly finished is it. This feature makes them marvelous indeed.

Here in the South we produce much honey that is naturally thin in body, which, in the extracted form, ferments to some extent and gives dissatisfaction on the market. It results about the same in the comb form, the capping bulging and sweating, and having a greasy appearance. Such honey is simply too thin to be wholesome. This is found not only in the South but in the North as well. The Caucasians, as a rule, evaporate this seemingly naturally thin honey and give it a good body, and it is

much more wholesome. They are very slow to cap such honey—so much so that it looks as if they do not intend to. This is another good feature in them worthy of much praise.

THEIR ONLY BAD FEATURE.

The only thing that has ever been brought up against these bees that I consider worthy of argument is that they are bad to propolize or glue up the interior parts of their hives, and often deposit this glue in balls of considerable size in the most remote parts of the hive, and especially about the bottom, causing annoyance in frame manipulation. Since I have had these bees I notice that this bad feature is gradually leaving them. I have partly brought this about by breeding from stock less inclined to do this. But with good wide-open entrances, front and back, they make their deposits of glue there, endeavoring, seemingly, to close up these openings where it is easily removed, and we no longer consider this an objection. It has been the experience of all that this gathering of propolis does not occur except during a honey-dearth. Is not this evidence

that they are great gatherers or very energetic foragers?

THEIR CROSSES.

I have crossed them considerably with my Italians, and I like the cross as well as I do the pure stock. In fact, the "dash" of Italian blood seems to combine the good qualities of both races, and make a great strain of bees, in some particulars preferable to the pure stock. It seems to a great extent to eliminate the desire to gather propolis and build burr and brace combs, and does not change their good qualities. The only bad thing about crossing these two great races of bees in this way is that the cross will gradually go out in favor of the Caucasians. This is accounted for by the fact that they raise more drones. In point of purity they are racially strong where Italians are weak. The reader should not think that I am condemning in the least the Italian bees. I have over one thousand colonies headed with pure Italian queens as near the \$20 mark as they can be bred, and I expect to keep them and add more.

Cordele, Ga.

FIGHTING THE ANT INVADER

BY E. S. MILES

On page 944, Dec. 1, 1914, F. H. Cooper writes an interesting account of the insect and bird enemies of the bees in South Africa. I had kept bees a good many years, and in four or five different places, before I found there was an insect enemy formidable enough to make real trouble here in Iowa; and this experience which I shall relate may be so exceptional as to have no practical bearing. In fact, I think one would meet with it very rarely, and yet, as Mr. Cooper says, it might be interesting to read nevertheless. The enemy referred to must be about the same ant Mr. Cooper describes on page 945 as being bee-eater rather than a honey-eater.

It is a large black ant, although, if I remember rightly, the fore part of its body is dark red in color. It lives in great colonies that gather small sticks and rubbish, and make a mound from 1½ to 3 feet in diameter, and perhaps a foot or more high. They also work down into the ground a foot or more, and in cold weather they go down and do not appear until the warm days of spring. On the first real warm days of spring, however, the top of their mound is black with them, and they can be seen running in all directions, going mostly in certain paths or lines. These lines will go

for several rods in all directions from the mound, the ants evidently traveling a regular route or trail. They are usually to be found in old brushy or woody pastures, hence are not often if ever found on farms that are rotated in crops.

In locating an outyard in the spring of 1912, in an old brushy pasture, never having heard of ants bothering bees in Iowa, hence thinking of nothing of the kind, I set a yard down right in the center of a circle of five or six monstrous colonies of these ants. I did not notice the ants until we had the yard all rigged up, and then we did not know that the bees could not win out in a "scrap" with the little black demons. On the contrary, we expected to see some ants very glad to go on about their own business shortly after we set the bees loose in this yard.

Near where one of these ant-trails ran through the yard we set what we considered a very vigorous colony of Italians—one that seemed very quick to notice and resent any intrusion into their domain, so we watched with somewhat pleasurable anticipation to see Mr. Ant get shown the way out when he (or she) began investigating the entrance to the hive. Imagine our surprise to see that, instead of Miss Bee grab-

bing Mr. Ant and showing him the door Mr. Ant ran right up to Miss Bee and grabbed for her! At this the bee turned, ran, and squealed, or whined, as Mr. Cooper calls it. To me it sounded like a squeal of fear. When the ants get hold of bees (they usually get them by the leg), the bees seem terrified, and usually fly away, ant and all. Sometimes a bee will get up courage enough to seize an ant, when they also fly away with them. I cannot say positively, but think from what observation I've had, that the ant never lets go. His grip is that of a bulldog, I believe, and while the bee rides the hive of one ant by flying, perhaps, far afield with him, yet it seems highly probable that the ant also holds the bee in a death-grip, so that she does not return. When we found that the ants would in a short time conquer the bees we got busy. We set one or two of the worst besieged hives up on stakes, painted around them with axle grease, and sent at once for kerosene. We took a sprinkler and sprinkled kerosene over all the ant-mounds, and along the main trails where they were traveling thickest, and set it afire. We used up probably a barrel of kerosene in getting the ants destroyed enough so that the bees were safe. We found that the remnants of colonies of ants would gather together and start business again, a handful or so seeming to be able to start a colony and recuperate again. But as the bees built up and became strong they would repel the few ants that would occasionally reach the hives from these. By prompt action we suffered no material damage to the bees the first season; and the next, while there were a few colonies of the ants, they were not populous enough to forage the beeyard, so the matter slipped our mind.

Last spring we again placed the colonies at this yard on their stands, and noticed the

ants were again quite numerous; so we intended to go over and give them another round with kerosene; but something prevented our going to this yard again for a couple of weeks. When we did reach the yard we found such a state of affairs as exists in Europe. War was on. One colony was gone completely—not a bee in the hive. I suppose they had swarmed out, and the ants had dragged off the dead ones, as not a bee remained, dead or alive. Several other hives were about on their last line of defenses, being huddled up on top of the combs with the ants all about the entrance, and dragging down a bee here and there whenever they could get hold of one. We managed to save all these, however, by setting the hives on clean bottoms, thus getting most of the ants away, and stamping those coming and going to prevent their getting into the hives. We again got kerosene, and, setting some of the hives away, we sprinkled the leaves and grass around the hive-stands with kerosene and burned it off. This burned space bothered the other ants so that it checked the attack on the hives, and in the mean while we again gave their mounds and runways the kerosene-and-fire treatment. After that we kept a heavy stamper, such as is used for firming the ground before laying cement sidewalks; and whenever we were at that yard we looked up all the remnants of ant colonies and stamped them with this stamper.

Yet with all this warfare on them I think there are yet enough ants within reach of that yard to exterminate it within three years, if left alone. We think these ants are a little the most persistent and about the "nerviest" creatures yet encountered. We are now debating whether to go on fighting ants or move the yard.

Dunlap, Iowa.

A REVIEW OF TWO GOVERNMENT BULLETINS

Observations of the Temperature of the Honey Cluster in Winter

BY R. F. HOLTERMANN

Before me lie two bulletins, Nos. 93 and 96 of the United States Department of Agriculture. The former is by E. F. Phillips, Ph.D., and his assistant, George S. Demuth, Washington, D. C.; the latter by Burton N. Gates, Ph.D., now of the Massachusetts Agricultural College.

In my estimation these two bulletins contain the report of some of the very best work ever done for beekeepers by government agricultural experiment stations. There

is abundant room for the beekeeper to find fault with much of the work done by various agricultural departments, if that work is supposed to be done in the interest of beekeepers, but the investigations reported in these bulletins are of a nature bearing directly upon a problem which is of the utmost importance to every northern or northerly beekeeper. The investigations and results recorded are none the less valuable because they (with scarcely an exception)

fully concur with the conclusions of our most careful beekeepers who have had time to make observations on their work. They agree with my own deductions, and give me further food for thought.

LOSSES FROM BAD WINTERING.

Dr. Phillips very well puts the results of the experience of the business beekeeper in wintering as leaving it "one of the most perplexing confronting the beekeeper, especially in the North," and attributing it to being "well nigh impossible to determine what external conditions are most favorable except by the gross results of experience."

Dr. Phillips is certainly not given to exaggeration when he states that "American beekeepers lose thousands of dollars annually in wintering, from the actual death of colonies, and even still more from those colonies that do not die, but are reduced in numbers and vitality." Few well-informed beekeepers would cavil with him if he multiplied the figure by ten.

CONDITIONS THAT INFLUENCE.

He states: "The factors influencing the welfare of the colony and the behavior of the bees are numerous, and closely inter-related. Of the chief ones may be mentioned external temperature, food, ventilation, humidity, the condition of the colony at the beginning of winter, and various forms of irritation."

The above points, in my estimation, pretty well cover the ground; and during a conversation I had with Mr. Morley Pettit when the experiment apiary was at Jordon Harbor, Ontario, giving him my views that the apicultural investigations ought to be carried on at the Ontario Agricultural College, Guelph, I stated that investigations in wintering ought to be carried on; that this should be done in winter repositories in which temperature, humidity, and ventilation would be absolutely under control.

The work in Ontario has not developed along the line that many of us hoped it would, probably due to a lack of funds necessary to grant for experimental work of the above nature.

DISTURBANCES.

Dr. Phillips and Mr. Demuth show in Bulletin 93, page 2, by temperature records taken from carefully placed electrical thermometers (which are much more sensitive and accurate than mercurial thermometers), that "disturbances of the colony may influence the temperature of the cluster for a considerable period, often more than one day."

In my cellar wintering I always considered it a small calamity to show any one

through the bee-cellar. Bees are much more sensitive to environments than we are. They can scent blossoms miles away. If we walk about a hive in summer without touching it the bees soon show disturbance. In short, their nervous organization is much more sensitive than our own. They are compared to us as the electrical thermometer is compared to the mercurial thermometer for recording temperature, only more so. The disturbance of colonies leads to changes of temperature which are the result of the increased consumption of stores, and, no doubt, lost vitality in the bees. Disturbances should, therefore, be avoided. When visiting the bee-cellars of others I have aimed at creating as little disturbance as possible, and coming out as soon as practicable.

DISTURBANCE FROM NEIGHBORING COLONIES.

The authors state, page 3, "Disturbances of outside colonies have also been found to influence their behavior in a pronounced manner, especially in cold weather." This is exactly the conclusion I have come to from frequent experiences; and to obviate this as much as possible I have said that every colony in a cellar should have a distinct base upon which to rest to prevent communication with others. Benches or long boards for cellar stands are bad. If we take a hive of bees, and place thereon four colonies, should one colony winter badly and become restless that restlessness is likely to affect injuriously all the bees in the pile, even communicating it to other piles in the proximity, doing damage in proportion to the length of time the bees have to remain in the cellar. My deductions were the result of outside observations; theirs, the result of the careful readings of temperatures, which is much more satisfactory and conclusive. For the same reason I condemn strongly a cement floor, also a board floor if it can be avoided. Separate stands should be used for each pile of hives. They are best on an earth floor with as little adhesion between particles as can be obtained, sand being better than clay. Then do not put too many bees in the cellar. I feel quite sure that in the cellar I built, 25 x 50 ft. outside, 7 ft. in the clear, 200 colonies will winter better than 400 or 500. I have always found some colonies more restless than others.

BROOD-REARING IN WINTER.

The authors, page 6, state, "The rearing of brood in winter causes a marked increase in heat production, and constitutes a condition which may become one of the most disastrous that can befall a confined colony."

On page 7, following this remark, we find the following: "If brood is reared, the work of the bee is necessarily enormously increased, and their vitality is correspondingly decreased. So far as evidence is available in this work, the colony is not fully recompensed for this expenditure of energy by an increase in the strength of the colony by bees thus reared." To this I would agree—activity results in reduced vitality; and nature, to supply this loss, brings on brooding to replace the lost vitality. Disturbing the colony results in a rise in temperature of the colony. If the bees have bad stores they will become restless, and the temperature of the cluster will rise; and a continuance of this will mean pronounced loss of vitality and brood-rearing. But with the confined and increased consumption there is an accumulation of feces in the bowels of the bees; the colony becomes more active, and this activity tends to dysentery. Take a colony with normal stores; confine it, then disturb it or place it under disturbing conditions, and it will soon have dysentery. In brooding the increased consumption of stores tends to fill the intestine with fecal matter; and that activity, for any length of time with flight, is not normal. Again, I know of no young animal which, during the building of its body, does not accumulate intestinal refuse of which it has to get rid soon after its own independent activities begin. I admit I do not know very much about this; but I have noticed the young bee void what I thought (and think now) corresponds to this; and my impression is that a young bee should have a cleansing flight soon after emerging from the cell.

THE LONGER THE CONFINEMENT THE HIGHER THE TEMPERATURE.

The observations in the bulletin show a rising temperature as the season of confinement is prolonged, and, with that, brood-rearing. This is just what we should expect. However, let me say here that the observations were taken with colonies which, owing to their location at Philadelphia, could have frequent flights throughout the winter. I venture to say, judging from the frequent examination of colonies in very early spring, that, the better the bees are wintering, the less brood will be reared, and the fewer stores will be used, other things being equal, and the less loss of vital energy in the colony.

THE INFLUENCE OF STORES—HONEY-DEW.

On page 12 we find: "In the case of colony 3, fed on honey-dew honey stores, the factor which caused more heat to be produced evidently increased much more rapidly. As stated previously, honey-dew

honey is a poor food for winter, and is so recognized. It contains the same sugars as honey, but contains in addition a considerable amount of dextrine, the particular lot fed to colony 3 containing 4.55 per cent, while good honey contains only a fraction of 1 per cent. From the evidence at hand it appears that dextrine cannot be digested by bees; and whether or not this is the explanation, honey-dew honey causes the rapid accumulation of feces, which usually results in the condition known as dysentery, in bad cases of which the feces are voided in the hive." The above, so far as the effect of honey-dew stores is concerned, can be vouched for by a great many northern beekeepers, and we may see the fruit of some such stores the coming spring.

Again, page 12, we have the following: "It therefore appears that the accumulation of feces acts as an irritant, causing the bees to become more active, and, consequently, to maintain a higher temperature. We are, therefore, justified in believing that the cause of poor wintering on honey-dew honey is due to excessive activity, resulting in the bees wearing themselves out, and, ultimately, in the death of the colony." This exactly coincides with practical results; and the reason why colonies which have not wintered quietly may spring-dwindle a great deal more than well-wintered colonies is because they have less vitality left, and succumb more readily under adverse conditions.

DYSENTERY.

On page 13 we find: "It therefore follows that excessive activity causes the consumption of more food, resulting in turn in more feces, so that colonies on poor stores are traveling in a vicious circle, which, if the feces cannot be discharged, results in the death of the colony. In the work here recorded no attention was paid to the theory that dysentery is due to an infection, since there is nothing in the observations made that lends any support to that idea."

The above confirms my opinion. What might make some believe that this dysentery is infectious is that it is liable to break out in colonies in the vicinity of the one affected; but as these temperature observations record, and as my previous observations lead me to believe, it is the disturbance which the colony with the dysentery communicates to others in the vicinity which causes activity, increased consumption of stores, brood-rearing, the accumulation of feces, and dysentery.

ACTIVITY IN CONFINEMENT.

On page 13 we again find: "While the activity of the cluster is greater at some times than at others, there are not, as has

been held, regular intervals of activity at which the colony rouses itself to take food. At no time is a colony kept at a room temperature of 45° F. or less in a condition which can be characterized as inactive. Presumably the reported intervals of activity have occurred when the colony made a noise due to disturbance by the beekeeper." I have never noticed colonies entirely inactive. That means a good deal; and I never saw a colony in which there were *no bees* moving. I never decided just how a colony took its food during the season of activity; but where the bees of a colony appeared constantly on the *qui vive*, and ready to fly at the light the moment it appeared, I decided it was wintering badly.

LONG CONFINEMENT AND POOR FOOD.

On the same page the authors state, "Keeping these bees in a cellar protected them from low outside temperature; but the lack of opportunity for a normal ejection of feces caused a condition more serious than extremely cold weather." Again, "Poor food is evidently a more serious handicap than low temperature. We must remember that in many sections bees, even if wintering outside, owing to continuously low temperature, are unlikely to have a cleansing flight during the entire winter. In my own section of country (Brantford) they generally but not always have a flight during midwinter or early spring.

FORMATION OF CLUSTER AND POSITION OF THE INDIVIDUAL BEE.

The formation of the cluster is then dealt with. We find the following on page 14: "The position with the heads inward is typical, except when condensed moisture drops on the cluster, as it often does in cool weather, when the bees at the top turn so that their heads are upward. The bees in the outer shell are quiet except for an occasional shifting of positions. Inside this rather definite shell the bees between the combs are not so close together, nor are they headed in any one way. . . . When the combs were separated the circle of bees in the shell was clearly observable. When a comb from the center of the cluster was shaken, the active bees in the center of the circle dropped off readily; and those in the outer shell, which were somewhat sluggish, were removed with more difficulty. After this was done, those occupying empty cells in the center of the sphere backed out of the cells and were shaken off. Finally, those occupying cells in the borders of the sphere backed out, showing a well-marked circle on the combs."

Any observing person who has pulled a cluster of bees apart in cold weather by

removing the combs will readily understand the above graphic description; and those who have not done so will have to read carefully several times before they can enter into the degrees of activity in the various parts of the cluster.

No doubt the hair on the abdomen of the bee makes such a cluster almost a non-conductor of heat. To do away with the dropping of moisture on the bees I am an advocate of absorbent packing above the frames.

VARIATIONS OF TEMPERATURE.

In Bulletin No. 96, page 12, Dr. Gates states: "During the period of most protracted cold, from Jan. 23 to Feb. 1, when the outside air ranged from 0° C. (32° F.), thermometer f followed the outside temperature closely, and the course of the two curves is practically the same. In some cases, as, for instance, on Jan. 26, thermometer f was slightly lower than the record of the outside air, which may possibly be explained by lack of ventilation, or stagnation of the air of the hive."

We must remember that these colonies were not in what beekeepers call winter-packed hives, and that, therefore, the air changed more rapidly than with packed hives; and with the more rapid circulation of air there would be a greater variation between the cluster temperature and the air below the cluster. Again, a variation of even only a few degrees, and that having to be kept up for the entire winter, would draw heavily upon the honey stores and also upon the vitality of the bees which have to generate the heat.

A HUMMING NOISE.

It has been a subject of controversy as to whether bees wintering well make any noise in the repository. I never entered my cellar (containing sometimes as many as 500 colonies) without hearing some noise; but I thought that perhaps it came from colonies more aroused than others. The authors on page 15, Bulletin 93, state: "That higher temperature may be produced, greatly increased muscular activity is required; and in colony C in cold weather, bees in the center of the shell of insulating bees were seen fanning vigorously, and executing other movements, such as shaking and rapid respiration. We thus have the paradoxical condition that bees fan to heat the cluster in winter as well as to cool the hive in summer. Observations of this kind were repeated beyond number; and the theory of the method of heat production is entirely supported by the repeated observation of a humming noise from the cluster during cold weather." The difference in the two above conditions is that in winter the heat is

conserved, while in summer it is driven away.

HOW HEAT IS GENERATED.

The following, page 15, seems almost incredible. "A few details of the observations on colony C may be of interest. For example, one bee was observed fanning vigorously for $7\frac{1}{2}$ minutes (9:53 to 10:00½ A. M., Jan. 23), while the other bees kept a space cleared for it. The temperature of the nearest thermometer rose $\frac{1}{2}^{\circ}$ F. during the time. At 9:52 this thermometer was almost a degree cooler than at the time of greatest heat during the fanning." Think of it! one bee raised the temperature $\frac{1}{2}$ degree; but perhaps the area was very restricted, the thermometer being close to the bee. Or by the fanning the air may have circulated so as to draw increased heat to the thermometer.

EXPANSION OF CLUSTER.

Dr. Gates, on page 17, states: "In watching this colony it was found that the density (and, consequently, the shape) of the cluster varied from day to day. When the air outdoors was warm, the cluster expanded; with cold, it contracted. The expansion usually did not cause the bees to cover more frames, but caused them to cover more completely those frames which they were occupying. Thus the expansion was usually downward toward the bottoms of the frames and in the direction of the entrance. With cold, the bees receded from the bottoms of the frames and from the top-bars."

Let me suggest that the reason why the expansion of the cluster was upward and downward, and not sidewise, is because of our artificial combs built on comb foundation, which does not enable bees to move sidewise to any extent unless the cluster

reaches above the top-bar or below the bottom-bar. In my estimation this is a handicap in wintering in modern hives and on straight combs. I should like to see the experiment conducted with box hives where the bees, when left to their own devices, will leave passages in combs so the cluster can expand or contract in every direction without leaving the cluster. The above is also a handicap when the bees want to change places in the cluster, and particularly when there are only a few bees on the outside combs.

On the same page we find "One of the most surprising observations was the apparent interchange of bees from the inside of the cluster with those on the outside of the cluster. As the writer watched the cluster, the head of a bee would gradually appear from below the bees forming the shell of the cluster. Finally this bee emerged, and took her place with the others on the outside. Similarly, bees were frequently seen to disappear into the mass."

I have written about this interchange and pointed out the desirability of having winter passages in straight comb so the change of position could take place freely. I also remember having a colony in a cellar where, by means of the number of bees showing under the bottom-bars, I could tell to a degree the temperature, and I verified this many times that winter, and compared the cluster to the mercury in the thermometer in the influence of temperature upon it.

The bulletins have many records of temperatures; but I have avoided dealing with them, taking only some of the practical conclusions reached. Would that we had the record of more such valuable work!

Brantford, Canada.

"PEACEFUL ROBBING," WITH SOME REMARKS ON COLONY ODOR

BY RALPH C. FISHER

In regard to friend Byer's experiences as given on page 839, Nov. 1, the following will account for the ease of robbing that resulted from his feeding bees. The outcome of it is hardly one of unusual character, but, rather, one wherein favorable conditions were inadvertently supplied to an insect always very willing and ever ready to take advantage of them. The season of nectar-gathering had long been past. The bees had taken on a restful mood, or, if you please, were manifesting a real inclination to stay at home. They were thus inactive because of no important duties to perform. A visitor to any apiary on these scattered balmy days, though

many bees are on the wing, will hear no industrious roar as when the nectar season is on. It was normally quiet, therefore, when Mr. Byer gave colony No. 8 that heavy feed of sugar syrup. It being a populous colony, the amount of feed large, and perhaps warm, the bees were attracted at once. I venture to say that there was a spasmodic return to general activity the moment bees began forcing their way into the dormant cluster in the brood-chamber. The result is likened unto the city fire department. On the sound of an alarm all is hustle and bustle, but in a systematic manner. There was probably a grand rush of

bees afield to ascertain the whereabouts of so much sweets. At the same moment there was a rush for the feeder. Plenty of feed at this late day certainly creates maximum excitement for the time being. Bees on the wing found the fields dry and dreary, and returned, therefore, only to go out again, then in an hour or so joined the throng making inroads on the feeder. The outward excitement having subsided, the restless thousands became reconciled to the one point of interest.

Thus Mr. Byer transformed his heretofore peaceable colony No. 8 into a teeming mass of robbers. If not the regular orthodox stealing one from another, it was essentially the same to the bees. Then, again, bees having once participated in such wholesale storing of sweets, the event is long remembered, especially by those of an advanced age. Aside from this there are always several members of a normal swarm continually going hither and thither, persistently seeking any sort of sweet that may be had with less effort than going afield. Vigorous colonies light in stores have this habit particularly—a fact easily proven by letting sweets lie about. Exposed sweets mean robbing, and robbing means a world of trouble; and if conditions are peculiarly favorable it means the total destruction of the apiary.

Now, a few days after Mr. Byer fed No. 8 he likewise fed No. 12. As the bees of No. 8 were all too keen for sugar syrup it was the natural course of events for them to seek out and discover the feed on No. 12 hive. Those old bees previously mentioned did the trick.

At the moment the bees of No. 12, with honey-sacs overfull, the brain absolutely excited, nerves all aflutter, the colony became practically the same as No. 8 as to condition. At such moments of excitement, orthodox rules and regulations are immediately discarded. Such colonies maintain an open doorway, so there was no opposition offered the bees of No. 8 when they came to raid the feeder of No. 12. According to impulse both colonies were of the same opinion, and the source of supply so abundant it needed no protection. Robbing bees are always too much inclined to rob rather than to resort to protective methods, and, like human beings of the evil class, strangely submit to one another's company. Mr. Byer rightly terms the episode peaceable robbing.

That night the bees of No. 8 returned home to dream of the fine time they had, and of what they were going to do on the morrow. The nights being quite cool it is

very possible the bees of No. 12 became partially if not wholly quiet during those hours, although with minds not unlike those in No. 8, for there were sweets yet in the feeder. However, next morning Mr. Byer removed the feed and feeder on No. 12; and as soon as it warmed up sufficiently activity began, and the loss of the feed became known at once. Consternation prevailed. The bees, being so anxious to steal, started right in to relocate the feeder. They then knew the exact smell of it; and the least aroma of that nature caused them to make a close inspection. Thus there was a second excitement, but of a different character, and bees of both colonies were again doing the same thing.

As before stated, both colonies were in an absolutely abnormal state with all orthodox laws repealed. Thus when the feeder was replaced on No. 8 the bees of No. 12 soon were at work on it through communication—rapidly so, from the result of previous robbing of their own feeder. Another thing, No. 8 had an abundance of unsealed sugar syrup in their combs, and it is very possible the bees of No. 12 discovered it on the day No. 12 was fed. At this juncture a feeder was replaced on No. 12 so that both had feeders. This act would naturally divide the excitement by establishing two points of interest, with the result that both colonies would gradually quiet down. The passing of a night would cause a return to normal conditions—more perfectly so if both feeders became dry at about the same time.

However, one can rightly suppose the bees of No. 8 and No. 12 continued to rob each other to a limited extent for some time. The most remarkable part of the episode is the fact that other colonies in the yard did not seek a hand in the excitement. The bees of No. 8 very probably first discovered the feed through the hole in the gable cover; and when the location of sweets became established they used the entrance at will. Mr. Byer admits No. 8 had been the lightest in stores, therefore more easily incited to rob. The majority of his colonies, amply and naturally provided for, were in a contented condition, with very few bees on the wing, these either playing or carrying water, and not so much inclined to rob.

As to colony odor in this case, the idea is a lost quantity. There is not a single factor in the case to warrant the use of the term. And here it might be said, though bees often manifest evidences of recognition through the influence of odor as regards bees and queens, the use of the term "colony odor" cannot be justified when applied to the

actions of complete or normal colonies. To prove the uselessness of the term, simply exchange frames of sealed or unsealed brood; make colonies queenless; introduce queens; make all sorts of various exchanges, when, in every instance, if odor has any

influence over them at all the same will be found to involve singly the bees, the brood, the drones, or the queen. Therefore colony odor has very little to do with the affairs of bees and their habitat.

Philadelphia, Pa.

ANNUAL MEETING OF THE MARITIME BEEKEEPERS' ASSOCIATION

BY E. L. COLPITTS

The annual meeting of the Maritime Beekeepers' Association took place in the board room of the Winter Fair building on Tuesday, December 7. A large number of the members, well representing the maritime beekeepers, were in attendance. More interest was shown than at any previous meeting. The auditor's report showed the association in good financial condition.

Reports of the season from many members were heard with interest. The presence of disease was reported from so many sections that it seems as if American foul brood has established itself already quite extensively in the maritime provinces. The honey crop had been light, clover not yielding in many sections. As far as reported, an average of 75 lbs. per colony was obtained.

J. A. Clarke, Charlottetown, P. E. I.; I. C. Craig, Amherst, N. S.; W. S. Blair, Kentville, N. S.; E. L. Colpitts, Petitecodiac, N. B.; and W. W. Baird, Nappan, N. S., spoke on the prevalence of bee diseases in the maritime provinces. Mr. Sladen, Dominion Apiculturist, had pointed out to the local governments the importance of stamping out American foul brood before it became established. As yet nothing had been done. A resolution was unanimously passed, urging upon the local governments the importance of passing foul-brood acts, and having them enforced by competent inspectors.

W. S. Blair, supt. of the experimental

fruit station at Kentville, N. S., spoke at some length on the importance of promoting the beekeeping industry, telling how it could be best done by the different provincial fruit branches. It was decided to present the importance of such a move by the fruit-growers, by sending a representative to each of the fruit-growers' conventions which meet in January. Messrs. W. S. Blair and B. W. Baker were appointed as representatives to attend the Nova Scotia fruit-growers' convention at Kentville, and E. L. Colpitts was appointed representative to attend the convention of the New Brunswick fruit-growers at Fredericton.

The following officers were elected for the ensuing year:

President, B. W. Baker, Amherst, N. S.

Vice-president, W. B. Wallace, Newport Landing, N. S.

Sec'y-Treasurer, E. D. Craig, Nappan, N. S.

Vice-president for Nova Scotia, Knox M. Lodge, Mapleton, N. S.

Vice-president for New Brunswick, W. G. Asbell, Sussex.

Vice-president for Prince Edward Island, H. Newson, Charlottetown.

Auditors, W. W. Baird, Nappan, N. S., and W. G. Asbell, Sussex, N. B.

Standing committee on exhibitions and prize lists, E. L. Colpitts, Petitecodiac, N. B.; G. W. Chappell, Amherst, N. S., and W. N. Tanton, Charlottetown, P. E. I.

Petitecodiac, N. B.

BEEKEEPING IN SOUTHEAST OKLAHOMA

BY FRED MYERS

Here in southeast Oklahoma we have, I suppose, a good average location for beekeeping; but it will be better when fully opened up and cultivated in the crops that should be raised. Along Red River (the line between Texas and Oklahoma), lying east and west, is a strip of black prairie land, rocky in spots. There are some good

farms, and on many of them alfalfa is being sown. Adjoining this on the north is rolling sandy timbered land, reasonably productive, with freestone water a few feet below the surface. On the whole it is a very nice-looking place to those hunting a location in the Southland.

But the country has been hard hit by the

present low price of cotton, which too many have been engaged in raising, instead of in giving more attention to food and feed crops, and orchards with hives scattered among them.

But the people see their mistake, and are casting about for something to add to the income on the farm. With the attention now being given by the United States Department of Agriculture, and all up-to-date farm papers, to both the honeybees and to sweet clover, we expect these to come into their own here and elsewhere.

Few places, I think, have more bees than this, considering the amount of modern equipment to be found here. There are hundreds of colonies in gums and boxes.

Our location is on the edge of the sandy country, so we should get the benefit of both sides. Our greatest discouragement has been the drouths of recent years. Usually the bees can start brood-rearing very early, the alders along the marshy branches furnishing pollen the first of February. The maples soon come into bloom, giving pollen and honey; then fruit-bloom comes in March; following this the black-gum and holly bloom, which yield nectar freely if weather is right—damp and warm; but, of course, we expect weather conditions to interfere with the bees' work so that we get only a part of the benefit of these different sources.

It seems that the greatest need is something to furnish a good flow during mid-summer, when we get the fine honey. I am not thoroughly acquainted with every thing upon which the bees depend, but I know cotton here is very uncertain, although extensively cultivated. It will be greatly reduced in acreage hereafter, and we are not sorry, as it is also a scant yielder with us. We have kept bees four years, and had all to learn; hence getting experience has cost us something. But we have always won some profit above yearly expenses, besides having honey for the home table. This alone is compensation for the work with bees. What kind of beekeeper would one be if he were not a honey-eater?

I also won both first premiums last year at our county fair for best comb and extracted honey. Besides, I may mention, but will not attempt to describe, the pleasures of beekeeping.

Recent articles in GLEANINGS on new principles in hive methods, etc., have been interesting reading, as we have been thinking of the possibilities of a larger hive; but the wintering problem is no argument with us.

Our ten-frame hives we think are hard

to beat. We use supers the same depth, all frames alike. We put full sheets of light brood foundation in these by the melted-wax one-fourth-rosin method. This does not fill the frame; but with proper management we get good combs joined all around, with not too much drone comb.

I am convinced the drones are of much more value than they are usually credited with, for this reason: We select males in improving anything else, and get the desired results, giving a large share of the honors to them; but with either good or bad results from queens, the drones, or male bees, are forgotten usually. Should we not at least divide the honors with them?

For fastening in foundation I use a china cream-pitcher, and think nothing is better than one holding about a pint. We set this on a warm stove with a paper-covered table near, having on it a pile of frames and some empty hive-bodies to receive frames when filled with foundation.

Taking a sheet of foundation I place it in the center of the top-bar of the frame which is held bottom upward with the further end highest, so the stream of melted wax will run freely along the edge of the foundation, fastening it to the bar. I then change the ends of the frame and wax the other side of the foundation the same way. These frames are not wired, and do not need to be. I work all best combs into brood-chambers.

Valliant, Okla.

Francois Huber

BY GRACE ALLEN

Brave? Who's brave? Have you heard of Huber,
Brave blind Huber, there among his bees,
Delying in their mysteries, searching out their secrets,
Seeing countless hidden things that only spirit sees?

"Blind? What's 'blind'?" cried the young stricken
Huber.

"Nevermore to see!" moaned his fast-failing sight.
"Always I shall see!" answered Francois Huber,
"Never, oh! never, need a soul lose its sight!"

He wedded with Love; Devotion was his servant;
These two looked and told him what they saw,
Offered him facts, and Huber's clear vision
Gave back truth, gave back law.

Blind? Who's blind? Not a man like Huber!
Soul looking forth through its own white light;
Give us, O God, men as clear-eyed as Huber,
With vision as sure as this blind man's sight!

Heads of Grain from Different Fields

The Backlot Buzzer

You can just bet a big red apple that anybody who is fortunate enough to be nailing ten-frame double-walled hives together these long winter evenings isn't going to lose any time playing peanuckle and dominoes.

Missouri State Convention Report

It may interest many of the readers of GLEANINGS to know about the Missouri State beekeepers' meeting held at St. Joseph. In many respects it was the best meeting the writer has ever attended. We had visitors from Indiana, Illinois, Iowa, and quite a number from Kansas. Mr. N. M. Jennings, Franklin, Ind., gave a good talk on wintering; and Frank C. Pellett, Atlantic, Iowa, one on preparing bees for winter, that was most efficient. Then of those of Kansas was Dr. Bohrer, a man 84 years young, and quite a number of others whose names we do not now recall; also M. G. Dadant and Mrs. H. C. Holmes, Belle View, Ill., and our own beekeepers from Missouri. We had a good attendance and an attentive audience.

We wish to mention Dr. C. R. Woodson, a man of large stature and extensive practice, and who is also interested in horticulture, who gave a most interesting talk on spraying. He fully agreed with beekeepers not to spray during bloom, as also did our Dr. Haseman, of the experiment station, an entomologist. It would take too much space to state all the good things we had.

It was decided to reorganize, and change the name to the Missouri Beekeepers' Society, and to incorporate. We hope thus to reach more beekeepers, and to

accomplish more for beekeeping in the State. We will also try again to get an amendment to our foul-brood law to make possible deputy inspectors. The necessity for deputies was quite apparent, as our present inspector had a long spell of sickness the past summer, and right in the time when the work was needed the most. We are sure that much more work can be accomplished by deputies, even if we do not secure any more appropriation, as deputies can be on the spot all the time, so that the inspector will not have to travel all over the State to reach the work. The deputies are to be under his control. We tried for this two years ago, and our amendment went through the senate with only one dissenting vote, and lacked one vote of a constitutional majority in the house of representatives. We feel that we can get what we want this time. It is surely needed if we are ever to get control of foul brood in our State. We now have a good foul-brood law, except that we need more help. Deputies, we think, will do the work, or at least much more than any one man is able to accomplish.

The new officers elected for the coming year are J. W. Rouse, Mexico, President; W. F. Cox, Garden City, Vice-president; J. F. Diemer, Liberty, Treasurer; Austin D. Wolfe, Parkville, Secretary. Mr. Wolfe is connected with the Parkville College; and as he is an ardent Y. M. C. A. man he made arrangements for the beekeepers to take dinner at the Y. M. C. A. building. We certainly had a good dinner and a fine time.

Mexico, Mo.

J. W. ROUSE.

What Constitutes an Ideal Wheelbarrow?

There have been many different kinds of vehicles invented and illustrated for handling honey and empty supers about the beeyard; and although a wheelbarrow seems to be the favorite with most beekeepers, I have not yet seen one illustrated that would suit me. Most people think all wheelbarrows must have the front slanting forward; but that is where mine differs from all other so-called handy barrows for a beeyard. I made mine 20 inches wide at the narrowest part of the bottom, and long enough to take three eight-frame hives, and the front is square from the bottom, so the hives will all stand on top of one another, and have no tendency to slip out of place, and that is quite a consideration when bees are inclined to rob. I can take nine empty supers in one load; but when I am taking honey in I place the hives lengthwise of the barrow so the combs will not have any tendency to crowd to one side. There is a shelf on the front for the smoker above the wheel, and a narrow box or pocket between the handles to catch any small bits of comb or wax. The front is made high enough so it will catch the third super, say about 22 inches.

REPORTS WANTED CONCERNING VENTILATED BEE ESCAPE BOARDS.

There is one thing I should like to get a number of reports on, and that is the ventilated bee-escapes, as to whether they work quicker or not. I made a lot last season, but the season was so poor I should not like to pass an opinion on the escape. The ventilating part is all right, but will they work as quick? I have my doubts; but I should like to hear from those who have given them a fair trial.

A WORD OF APPRECIATION FOR THE INDEX.

I can't help writing a few lines of appreciation for the GLEANINGS index for 1914. It is a pleasure to hunt up any article in this index. For the last several years I hated this job; for with the index as arranged it was a good deal like hunting something out of a barrel. I have many times

thought of trying to get you to change to the present form, but I didn't want to be called a chronic kicker. There is only one thing worse than the old index, and that is no index at all.

I have been shining as a kicker against our *Canadian Horticulturist and Beekeeper*, as the publishers refuse to print an index. It certainly reduces the value of any journal to be without an index. I know in my case I have many times wanted to look up information on a certain point, and have taken down 15 or 20 journals (I bind all mine), and it is wonderful the amount of information a person can get by just looking at an index.

Forest, Ont.

I. LANGSTROTH.

Decoy Hives in Rhode Island

I was very much interested in the article relative to decoy hives by our good friend Dr. A. F. Bonney, published in the *American Bee Journal* some months ago, so I decided to try the plan. I procured at a local grocery a dozen wooden boxes about the size of a hive. I tacked in some slats to act as frames, and to one I tied a piece of comb.

I made an entrance at one end about one inch by eight, and made a door that would close down over the entrance, as indicated by the doctor's drawing in the article. To keep out rain and dampness I tacked a piece of cheap enamel cloth on top of each box, and tied on the cover with strings.

As there is a great risk that each box may not catch a swarm, or may even be stolen, one has to try every way to make the expense as light as possible.

Several of these boxes were placed in the crotches of apple-trees. One was placed on top of a ledge of rock; another in what was once a window in the ruins of an old stone mill; a third in a pine tree; and, the last of all, on a partly tumbled-down chimney where a farmhouse once stood. In fact, all of these boxes were set in the country, and mostly on deserted farms.

Bee-hunters are quite plentiful through the country districts of Rhode Island, hence setting bee-boxes is a little risky. Even though the owner's name may be on the box, it is not always respected, because a colony of bees that costs nothing is usually very acceptable to almost any one.

Of the twelve boxes that I put out, the one placed on the tumbled-down chimney did the trick and captured my only swarm. Last spring bees did not swarm very much in the country districts of Rhode Island. One man whom I know has eleven colonies of bees in the old-fashioned box hives, and had only three swarms before the first of July, while the others swarmed later on. One of the best bee-hunters in the State informed me that he and his companion have located only four this year, while they located ten last year. In fact, I am of the belief that here in New England wild or escaped bees are growing scarce.

From my experience in setting bee-boxes, I do not think it pays here. I also believe that a box, to have any chance of catching a swarm, must be set in a very conspicuous place. Then in such a place others may appropriate the good luck before the owner does.

Bees Plug the Horizontal Openings in the Top-bars with Wax

The letter on page 1000, suggesting horizontal openings through the top-bars for winter passages for the bees, reminds me of some experiments that my father, the late S. T. Pettit, tried many years ago. I can still remember seeing combs in the brood-chambers with these holes through the top-bars securely and hermetically sealed by the bees with wax. When friend Bordon tries out his idea he

will find that the bees will wax up the openings, and I imagine he will decide that other ways to provide the winter passage are better.

Another method that S. T. Pettit had in making winter passages was to bore through all the combs of the brood-chamber in one operation by means of an iron rod heated in a kettle of boiling water. One of my earliest recollections is having to sit beside the hive, holding a form while he bored through with this instrument. Holes were placed in the sides of the hive and kept plugged except when the combs were to be bored out the last thing before the bees went into winter quarters.

I do not think that any thing will take the place of the Hill device or some similar arrangement which gives a passage across the top-bars.

Guelph, Canada, Dec. 28.

MORLEY PETTIT.

Plan for Fastening Foundation

I notice in GLEANINGS, 1913, page 799, H. H. Root's plan for fastening foundation in frames, which is surely good; but I do not understand why he wants the lower wire to curve upward. Here in Texas we use two wires where four holes are already punched. We put one wire in the second hole from the top and the other in the fourth hole, as

shown in the diagram, and then with short pieces of wire wrap one end two or three times around a tack and drive it about the middle of the top-bar. We pull the horizontal wire tight in the middle and wrap the wire around. Next we tighten the second wire and wrap the end of the short wire around it. It surely will not sag nor buckle. Instead of a tack we sometimes wrap the wire around the top-bar.

Angelita, Texas.

Who Should Worry over the Net-weight Law?

I have just read with considerable interest the editorial, page 921, Dec. 1, on the net-weight law as applied to comb honey. My inference is that it would make no difference whether the section was weighed in or out. A practical beekeeper or honey jobber isn't going to mark the *exact* weight on each comb, is he? Is it necessary to mark the maximum weight on each section of honey? Why not grade the honey as formerly, and, when cased, stamp each section alike with the minimum weight, say 10 or 12 or 14 oz.? Suppose there was not a section in the 10-oz. case that weighed less than 14 ounces. Whose business would it be if we gave the customer 4 ounces more honey?

I spent three weeks recently selling extracted honey to dealers in eastern North Dakota and western Minnesota. I had the opportunity of seeing several hundred cases of comb honey in the hands of dealers there, and I gave it some attention. One producer marked with a pencil; some more had "not less than 12 oz.," but the concern that supplied most of the comb honey in this section had each comb stamped the same, "Not less than 10 oz."

If this fills the letter of the law, why worry over the weight? This was all nice honey, and probably weighed 14 or more ounces, with a few exceptions. Now and then a case had some thin combs, probably 11 oz. Under our standard grading we would grade this out; but under this plan of weighing we would not need to. This net-weight law is supposed

to be something for the consumer, is it not? In this particular case it would look as though these law-makers had handed us another chestnut.

Massachusetts Meeting

The recently organized Massachusetts Society of Beekeepers held its monthly meeting on Saturday, Dec. 19, at 28 School St., Boston. The speaker was Hon. George F. French, of the Federal Department of Agriculture, Washington, D. C., who spoke on the profits Massachusetts has in honey production. The speaker brought out how the beekeepers could bring Massachusetts to the front line as a honey-producing section.

Ten new names were added to the membership list. The next meeting will be held in January at the call of the secretary.

Rutland, Mass., Dec. 23. P. D. HANSON, Sec.

Treating Foul Brood in the Winter

We have two colonies of bees that we think have foul brood. They cannot be treated now. What can we do to save the bees over winter?

Massillon, Ohio.

F. G. KAUFMAN.

[The only thing that you can do is to see to it that they have plenty of stores to carry them through, and that they are comfortably packed. Treatment should be given as soon as settled warm weather sets in. If they were bad with foul brood last fall it is very probable that they will die out before spring. Care should be exercised that the honey be not robbed out by healthy colonies during the first flying days.—ED.]

Queens above Excluder

Having noticed of late that several writers for bee-journals have been discussing the raising of queens above an excluder, without arriving at a settled opinion as to the advisability of doing so, I venture to offer my opinion.

A young queen can be reared and fertilized in the second story above the excluder in a strong colony. But, *don't do it*. It does not pay for the trouble. There are too many frames and bees to hunt over; and if by any means you fail to find it at the right time it will take twenty to thirty pounds of honey out of the crop—enough to buy two or three queens without the trouble. I sometimes put a frame of young brood in such a colony, but take care of the queen-cells before the young queens emerge.

La Valle, Wis., Dec. 9.

W. L. ROBERTS.

Push-in-Comb Plan of Introducing Com-mended

Responding to the invitation, page 923, Dec. 1, I wish to add my mite in favor of the push-in-the-comb-cage plan of introducing queens. I have practiced this plan this year, and every year for the last eighteen years. I always recommend this plan to my customers when they ask me for an infallible method of introduction, and I have yet to know or hear of a single failure where this method was used.

I always recommend to my customers that they leave the hive severely alone for a whole week after introducing the queen this way, to give her a chance to get to laying before the bees are disturbed again, as any queen is liable to be balled if disturbed before she gets to laying. I also recommend that the cage be so placed as to include some honey, some hatching bees, and some empty cells for the queen to begin laying in. I do not care whether there are any larvae enclosed or not.

The only objection I see to sending out instructions to use the push-in-the-comb-cage plan, besides

the objection you mention, is that it is more trouble to make the cages than the average beekeeper will take. Sometimes we have orders for 25, 50, or 100 queens. It would be quite a little trouble to make up so many cages; and often the beekeeper has not the wire cloth handy to make them. Perhaps it is fifteen or twenty miles to the nearest store where the wire cloth can be obtained. In that case the man may be without any information as to how to introduce. Shall we send the wire cloth with the queens?

I have tried the smoke method of introduction. Usually it works. Sometimes it does not, and I don't see why.

Mathis, Texas.

H. D. MURRY.

Would See Farmers Keep Bees

In reference to the experiences of J. S. Miles, page 946, Dec. 1, I will say that I see the matter altogether differently. First, the farmer has a right to try his hand at beekeeping, whether for success or failure, and he creates a demand for bee-supplies as well as for honey. For example, last week I sold five gallons of honey to a Mr. Owens to feed his bees, as he had had an off year. Now, Mr. Owens never would have bought five gallons of honey had he not been in the business. The past two years Mr. Owens got considerable honey and sold some to his neighbors, who this year also came to me. He has worked up a market by educating the people to know that honey is pure as well as very healthful, and he had told his neighbors that my honey was pure, and sent them to me. I have sold him the bees and the hive at a small profit. The honey that was gathered would have gone to waste.

Give the farmer a little reading on bees, and tell him by all means to get the good bee-books for information. Give him one about hives and show him how to use foundation, and how to put up honey. Only by attempting the work blindly can real disaster and discouragement result.

Palmetto, Fla.

C. H. CLUTE.

Wires Preferred to Splints

P. S. Reaves, page 942, Dec. 1, describes the trouble just as it is here. My bees began to die in the latter part of August. I would find 50 to 150 dead bees, mostly young but perfect, on the alighting-board every morning. At first only one hive was affected; later, others. We had very dry weather here through July and August, and more honey-dew was stored than I ever saw before. Other beekeepers here had the same trouble. It cannot be poison nor anything gathered; for, if so, all the colonies would be similarly affected. Do you not think so? About one-third of my colonies had the trouble. Nothing that I could find upon examination caused the dying, some having little honey and some plenty.

I have tried the Miller splints to my (dis)satisfaction. Hereafter I shall stick to wiring full sheets. I tried, the past summer, a few frames without grooves or comb-guides or wedges.

I placed the top wire $\frac{1}{2}$ inch below the top-bar; and when fastening foundation I pulled the wire lower $\frac{1}{4}$ or $\frac{1}{2}$ inch in the center, the second wire the same (as described in instructions sent with foundation). This forces the foundation up against the top-bar, and in every instance the bees fastened it nicely. These frames were put in between built-out combs. Next season I will try with swarms.

Asheville, N. C., Dec. 14.

O. BROMFIELD.

More about that Mysterious Trouble

In reply to P. S. Reaves, Princeton, W. Va., page 942, Dec. 1, I will say I have the same trouble here. I have 26 colonies of bees, and went through them two weeks ago and found honey enough for

the winter, but no brood in any of them. Only a small quantity of bees were living, and they are still dying by the handful. I don't think I shall have a colony left for spring. My apiary is located in the back yard of my lot in the middle of our city, and I have been only five years in the business.

We had such a drouth in this section that there were no blooms for the bees to work upon until late in the fall. There were enough for them to lay up for winter.

East Radford, Va., Dec. 9. R. H. CREASY.

Farmers' Insurance Co. Insures Bees against Fire Loss

I have read the letter of inquiry about bee insurance, page 956, Dec. 1, and your answer that you have been informed that no company will insure bees against loss by fire. We have 170 stands of bees insured for \$400 against fire and lightning, in storage and out, by the Farmers' Insurance Co., Cedar Rapids, Ia. The liability is \$3.00 per stand in case of loss. There was no trouble about getting it. The agent wrote in for instructions, and permission was given at once.

Turkey River, Ia. L. W. MAXWELL.

Retail Your Own Honey

There is one method of marketing honey that is rarely mentioned in any bee-journal, and I beg to suggest that it be discussed in GLEANINGS in 1915—that is, the bottling and selling of extracted honey by the producer. Go into groceries where you will, and you see bottles and jars of honey on the shelves. On closer examination you will see "This honey was put up by — Packing Co., or "Bottled by — Bottling Co." Why cannot beekeepers supply their local grocers at least, or retail it to the consumers in the nearby towns themselves?

Some beekeepers object, saying that they have not the time to bottle honey; but I know that there must be scores like myself who have but little to do in winter, and many no doubt have a heated workshop or honey-house where the work may be carried on. Surely there must be some who bottle and sell part of their honey in small packages, and I am sure they will be willing to give others some hints on the subject, such as best methods of bottling, selling, etc., and best size of bottle to use.

Every beekeeper who retails his honey should be prepared to furnish honey in any form his customer desires it. Thus, if he produces comb honey only I believe it would pay him to purchase extracted honey from a producer of that article, or exchange with him and *vice versa*. Beekeepers cannot give too much study to the selling of their honey.

Catskill, N. Y., Dec. 28. ELMER W. PALMER.

Beekeepers near Akron, N. Y., Organize

We held our meeting at Akron, N. Y., Dec. 15. The day was rather stormy, and the crowd was not as large as would have been the case had the weather allowed. Those present had an interesting time discussing timely topics.

One member has a trying time every year keeping pollen out of his sections. At first thought it would seem this is a question of carelessness, but not so, as Mr. Sprout is an intelligent beekeeper and not to be misled so easily. He says it bothers him every year from the beginning of the clover flow to the end, in colonies before swarming and after. Young and old seem to make no difference. He uses a frame nearly 12 inches in depth, and hives his swarms on two empty combs, and does not put on supers immediately, but still the trouble is there. If he puts an empty super under a partly filled one, in goes the pollen and sometimes on top. He has

tried almost every thing conceivable, even putting drone foundation in sections, but of no avail. Can any of the readers offer a remedy?

A local organization was formed with the following officers: President, John N. DeMuth, Pembroke, N. Y.; Vice-pres., J. Roy Lincoln, Niagara Falls, N. Y.; Sec'y-Treas., William Vollmer, Akron, N. Y.

A summer field meeting was also decided upon.

Akron, N. Y. WILLIAM VOLLMER, Sec.

[Bees are creatures of habit and they must not be allowed to get the habit of placing pollen in the sections. We presume that Mr. Sprout recognizes this fact and that he has done all in his power to prevent them from doing so. An occasional cell of pollen in comb honey seems inevitable, but if there are combs containing some pollen at each side of the brood-chamber with plenty of empty cells for more, the trouble is not likely to be serious.

Some have used a queen-excluder which also serves as a pollen-excluder usually, but if possible the situation should be controlled in some other way.—Ed.]

What to do when a Swarm Issues

When running for comb honey, no matter how much room or ventilation is given the colonies, some will swarm. This is my way of treating them. I watch at the entrance for the queen (of course I have the queens clipped); and then I cage her and lay the cage at the entrance of the hive that the bees came from. Then while the swarm is in the air I go through the hive and cut out the queen-cells. At the beginning of the season I put back four or five frames of brood in an eight-frame hive, and fill the rest of the space with full sheets of foundation. At the latter part of the season I put back six or seven frames of brood, filling up with full sheets of foundation. About the time I get through the colony the swarm will return. When the bees are about half in I let the queen run in with them. The brood that is taken away from such colonies is given to weak colonies.

Juda, Wis., Dec. 8. JAMES D. BENSON.

Ames Bottom-board for Four Hives Faulty

The Ames bottom-board, p. 889, Nov. 15, is faulty in this respect: When the colonies are very strong, the weather very hot, and a sudden check occurs in the honey, the bees from the south hives will often get up a nice scrap with their north neighbors, and a lot of dead bees will be the result; then when young queens are mating they too often return to the wrong hive. Now, if he will tack the cleats on the bottom of the hive with short nails so they can be easily removed, he can, when he takes off the winter case, move the hives to the extreme ends of the bottom-board and place a wide shingle on edge next to the north hive, and have things more harmonious. I have been through the mill.

SUBSCRIBER.

A Beekeeper who has not Walked for nearly 40 Years

I am 43 years of age, and I have not walked for nearly 40 years. I was stricken with infantile paralysis in both feet and legs in 1876 when I was five years old, and have never walked since. My feet and legs are very small. I cross my legs by laying one foot on one thigh and the other on the other. I have leather pads filled to put on to crawl on, and also leather slippers, as I call them, for my hands. I am strong in my arms and body, and crawl about my little apiary and shop, which is also my honey-house, and work with my 43 colonies.

When I was 17 years old I crawled half a mile to hive my first swarm.

Woolwine, Va. JESSE G. COCKRAM.

A. I. Root

OUR HOMES

Editor

ROBBING SICK PEOPLE; GYMNASICS IN THE GARDEN, ETC.

I think most of our readers have seen advertisements of wonderful things for the cure of sick or ailing people in the shape of treatment by mail, correspondence schools, and other things along that line. From the very first I have been suspicious of some correspondence schools;* and I have invested money in them in order to find out how they work. I have already mentioned the one for the cure of failing memory. A great doctor made wonderful promises about treating each case individually. I think his price was \$20.00 for the whole course. If you did not "bite" at the \$20.00 tuition, after a week or two come particular reasons why he has come down to \$10.00. If you do not jump at the reduced offer, a few weeks later the price is reduced from \$10.00 to \$5.00; and I do not know but they come down still lower later on. One of our subscribers bit at the bait, and sent me the whole course of treatment. Instead of its being a personal letter for the particular individual, it was simply a lot of printed sheets that, even if they were of any benefit, could be furnished for 25 cents. There was hardly a new suggestion, nor any thing that has not been known for years.

Some time last spring I saw an advertisement of a course of instruction in massage, or something of that sort. It was a way of developing the muscles wonderfully, accompanied with a picture of a model athlete. As I have been for some time curious about such a treatment I sent for particulars. It did not impress me very favorably, although the writer laid strong emphasis on sending the money back if the customer was not perfectly satisfied. He said Uncle Sam would not *permit* him to use the mails if he did not "make good" all his promises. I hope the above is true; but if it is, it is news to me. Well, I laid his papers aside; but in the course of a month or so he wrote that he had been anxious about my case, and wanted to know why he did not hear from me, offering to cut the price down to \$10.00 for an immediate reply. I then wrote that there was no need of sending me any more "form letters;" but if he wanted to send me the treatment, and it proved to be of any benefit to me whatever, I would forward the \$10.00, referring him to Dun and Bradstreet for my standing, also mentioning the fact that I did not find *him* quoted at all. For

* Some are good and are operating on the right lines. With these I have no quarrel.

the first time I got a *real letter*; but I *may* have been fooled even then. He said that doctors like himself are not quoted by Dun and Bradstreet, and the only way he did business was to have cash in advance. I supposed this would end the matter; but in a few days came another form letter, skillfully planned, to make it appear like a personal one to myself, saying so many of his friends had told him how much *good* he could do by reducing the price still further he had decided to offer the whole treatment for the next ten days for the ridiculously small sum of \$5.00. I especially wanted to see if the money was coming back promptly if I felt I had received no benefit, or if I were not perfectly satisfied with the investment. Now, right here comes in a "kink" that I had not thought of. The full treatment to be gone through with night and morning is for 90 days. Well, my opinion is that the average person would become so tired of the "gymnastics" before the 90 mornings or 90 days were over, that he would be likely to be willing to let his \$5.00 go rather than to keep on. The conditions were that you follow the treatment faithfully; and I have enough confidence in humanity to think that there are very few who would declare they had kept it up nights and mornings for 90 days when they had not done so. Regularly every week so far comes a form letter giving additional information. Now comes the question, "Have I not received some benefit?" Yes, I think I have; however, very little of the instruction was new to me. The course of gymnastics in our schools amounts to about the same thing. For a person who is kept in an office all day, and does not have sufficient exercise outdoors, there would, no doubt, be much benefit from it. For instance, one of the latest exercises is to sit down on your toes and then straighten up, say a dozen times or more, providing you do not get *too* tired. This is all right and good; but one who works in a garden has about enough of it in picking strawberries, beans, etc., without having the same thing to do night and morning; and I am inclined to think the vigorous use of a hoe, night and morning, would develop the muscles in the arms about as well as the gymnastics, and something would be *accomplished* instead of just swinging your arms like Don Quixote's windmill. This treatment is certainly far more commendable than the advertisers who doctor with drugs and new-fangled medicines. It cannot do you any harm, even if it does not

do you any good; and I have heard it urged that, unless you pay five, ten, or twenty dollars you may not take the pains to carry out the treatment. This may be true; but it is a rather sad reflection on humanity. The principal thing I object to is the practice of having form letters printed in such manner as to appear as having been type-written. The *Sunday School Times* says deception is *always wrong*; and the Bible says so too, but perhaps not in just so many words. Now, these form letters, skillfully planned to make you believe the great doctor has actually written to you, having nobody else in mind, are, in my opinion, mailed with the purpose to deceive. Several times lately I have carried such letters to our Mr. Boyden, who is an expert along this line, and asked him if the letter in my hand was printed or written; and sometimes it bothers even him to tell. The "A. I. Root, Medina, O.," is unquestionably put on with a typewriter; but the shade of ink agrees so perfectly with the body of the letter that it is hard to determine. While I severely censure this form of deception I am well aware that some of our religious denominations are making use of this scheme.

Some of my friends think I am too severe, and suggest that people will take more pains to read a *letter* than they would a printed leaflet. Even if this is true, I am sure that in the long run it *pays to be strictly honest*. It is well enough to use every honest means to attract attention and to get people to read what you want them to know; but is it not very much better to avoid deception of any kind—to avoid even the *appearance* of evil, as we have it in the good book?

Last, but not least, is it honest to take \$20.00 for something you have to sell if you can, then wait a while and start up some excuse for offering the same thing for \$5.00 or even less? My oldest granddaughter, who is just now at school in Oberlin, tells me, in talking over the matter, that one of the text-books in their school warns the public against quack doctors who advertise "treatment" for \$20.00, then \$10.00, then \$5.00, and so. Is it *honest* to take \$20.00 from unsuspecting and confiding people, and then let others have the same thing for \$10.00 or even \$5.00?

In conclusion, let me ask once more, are these persons and firms who are attempting to obtain your money by mailing these form letters to you in the manner above set forth any better than pickpockets in general? I think not. Call your family physician (your neighbor and one whom you *know*), when you are ailing, and get his advice.

I always tell our doctor I would much rather pay him for *advice* than for medicine. Far better give your money to honest men whom you have known for years than to hand it over to pickpockets.

I forgot to mention that the instruction is to finish up with a sponge bath after each course of gymnastics. Now you can all have the benefit of it, *without* paying twenty, ten, nor even five dollars. Oftentimes I feel too tired to go through my exercises before retiring; but after I have thrashed about and got well warmed up, and perhaps a little tired, and then wind up by rubbing myself with my wet hands all over my body, and getting scrubbed off with a towel, I feel tiptop. In the morning our bathroom is generally a little cold, and oftentimes I feel reluctant about taking a sponge bath. Well, after the exercises it is just fun to wash all over, as I have recently described, then have a good rubbing with a towel. Then I do not mind the cold a bit.

“OXYPATHY” FINALLY GETTING ITS JUST DUES.

See below, clipped from the *Rural* of Nov. 28:

“OXYPATHY” FINALLY GETTING ITS JUST DUES.

The oxypathor has at last been adjudged a fraud by a court of law. The Federal court at Rutland, Vermont, found the manager of the Oxypathor Company, of Buffalo, N. Y., guilty of using the mails to defraud, and he received a sentence of 18 months in the Federal prison at Atlanta, Ga. This scheme seemed to have been operated by several companies which controlled certain territory. Besides the one in Buffalo there was one in New York city, which was driven out of business some time back by the Vigilance Committee of the Advertising Men's League. There was also one in Chicago, and another operated at one time from some point in Pennsylvania.

The oxypathor is a small box filled with sawdust and some other inert matter. It is provided with a cord at each end; and the patient was to attach one string to his head and the other to his feet. The claims were that this would cause an extra amount of oxygen to be forced into the blood, and that a cure would follow. Doctors and chemists who examined the box and analyzed its contents invariably asserted that the matter was inert, and could have no physical effect whatever on the patient. The cost of the instrument was \$35.00. They were sometimes sold under guarantee; but we were never able to get the cash returned. We exposed it several times in the past, but the advertisements appeared quite regularly in papers of high and low degree.

COMING TO FLORIDA TO SPEND THE WINTER, ETC.

As I have been having quite a number of letters of late, similar to the one below, I submit this one with the answer I have penned on a postal card.

A. I. Root:—Having learned through GLEANINGS of your making your home in Florida during the

winter months, and that possibly you have some knowledge of that State, I would ask:

Would you advise a young man to go to Florida to spend the winter?

Which part of the State is best as regards climate? Are the people Christians? Is there any work?

About what would it cost to go and spend a winter there?

I will give you in short some information as to myself. I am twenty-three years old; was raised on the farm, free from any appetite for liquor or tobacco, and can give reference as to my character, such as The Farmers and Merchants Bank, Winchester, Ind., and as many more as you would want.

Winchester, Ind.

ALVA O. WEIMER.

I would not on general principles advise a young man to come to Florida now, with a view of getting work. The war has hurt us in two ways—cut off potash for fertilizer, and cut off the market for cotton. The climate is desirable here because there is seldom any killing frost. There is also a large body of nice Christian people here. A trip here and back would cost you toward \$50.00, and board toward \$1.00 a day. You can, however, rent a room, or even live in a tent, and save a lot. If you have no trouble in getting work where you are, you might be able to find a job here. Handy skilled men are always wanted almost everywhere. A. I. Root.

In answering the above I realize most vividly how hard it is to give advice to one we do not know. One who is never at a loss for something to do, and one who delights in helping the *world* along, will find great opportunities here in Florida; but one who depends on some one else to find him a job, and who is for the most part planning only for *self*, had better not come here, or, I almost said, *go anywhere*. He had better stay where his neighbors and relations can look after him. One who is expert in *making things grow*, and who can, by watching experts, learn to get like results, will find this a grand place to work and study. I would, however, advise such a one to have a little money ahead, for he may have to take time and expense before he begins to get returns. Go over my talks in this department for the last four or five years before you start out and you will find it a *good investment*.

HIGH-PRESSURE GARDENING

CASSAVA; NOT ONLY GOOD FOR "CHICKENS"
BUT ALSO FOR FOLKS.

A year ago, when we reached our Florida home about Nov. 1, I mentioned asking Wesley how those big spreading trees came right in a prominent place in our garden; and when he replied it was the cassava I could hardly believe all that growth had come from the little sprouts just peeping out of the ground six months before. Well, after giving some of the roots to the chickens I became so enthused that we used all our spare wood for making cuttings; and when we left Florida, the last of April, we had planted two beds, perhaps 200 feet long by about 10 feet wide. I have told you how we sawed up the branches into pieces about as long as corncobs, and placed them close together in a "cutting-bed" until they started to grow. When each one had sent up a little shoot they were planted in the long beds four feet apart, making three rows—one down the middle and one on each side. Well, when we got here again in the fall I had another "happy surprise"—two beautiful *groves* of bright-green thrifty-looking trees with scarcely a failure. One of these beds was on the poorest dry sandy spot we have on the premises, and I told Wesley I felt sure the cassava wouldn't amount to any thing, as we had tried different stuff, and every year it was "no good." He declared, however, cassava did best on poor sandy land, well drained, and there was a deep ditch right close to the fence, for

carrying off the storm water. Before setting the plants we did give the bed a little poultry manure and some fertilizer right in the furrow when the cuttings were planted. The little trees soon shaded the ground so that very little cultivation was needed.

About the middle of December I decided to use the bed where my first cassava-trees grew—the ones that had been growing two summers, and told Wesley to give the roots to the chickens and forgot all about it. As he started home at night he was eating something that looked like a big peeled turnip. It was a slice from one of the cassava roots.

"Why, Wesley, is that good to eat raw?"

"Sure! and it is good to eat baked, just as you bake potatoes. Try some and see."

Now, the government bulletin says that, while the two-year-old roots are much larger, they are not as sweet and tender for stock as those of only one summer's growth. I went and looked at the root where Wesley got his "slice," and it was bigger and longer than my leg. I got the ax and supposed it would take quite a blow to sever the root; but the ax went through and down into the ground, as the tuber was so tender and brittle. It took quite a while to bake; but I was rejoiced to find it a nutritious and quite delicious food. Mrs. Root, however, doesn't quite agree with me. She says I always like *any* thing new; and perhaps it is true that I always rejoice in finding something I had never come across before in the

way of "God's gifts."* With the ax I cut from the root (it was five inches in diameter and weighed 18 lbs.) several cylinders and stood one on end in the chicken-yard. Passing there half an hour later it had disappeared. I gave them another, and pretty soon the ducks came up from the canal and there was quite a noisy combat as to who had the "best right" to the new delicacy.

Well, if cassava will take the place of corn for ducks, or even partially replace corn, at 35 cts. a dozen for duck eggs (hens' eggs are 45), we shall have a bonanza here in Florida.†

Now, the above isn't *all* of my story. The cassava-tree that had grown two summers had three other roots, for there was a cluster of them, though not as large, and several roots were taken from it when it had grown only one summer. If you want to know more about cassava, send to the Department of Agriculture for a bulletin. See page 280, April 1, 1914, in regard to cassava as a food product.

GOLDEN APPLES AND DELICIOUS APPLES FROM OHIO TO FLORIDA BY PARCEL POST.

Prof. W. J. Green, of the Ohio Experiment Station (a lifetime friend) was kind enough to send us half a peck each of two noted apples by parcel post. When our Ohio station was established in Wayne Co. years ago they took an old run-down orchard and made it a wonderful object-lesson for rising generations. By trimming, fertilizing, and grafting, they have not only made it "a thing of beauty" but it *almost* promises to be "a joy for ever."‡ In the nearby zones such apples by mail may be, without question, a big success. Below is what I wrote friend Green:

Friend Green:—Many thanks for the beautiful apples you have so kindly sent me. They are not only beautiful to look at, but the finest-flavored apples, I do believe, I ever tasted. If the postage were not so much this long distance there would certainly be a great opening for apples by parcel post. The "container" you used brought them in splendid condition. Not an apple was bruised or injured in any way. The "Delicious" apples you send are certainly more delicious than the samples sent me some time ago by the Stark people in Missouri; and the Grimes Golden, even Mrs. Root admitted were pretty near the best apple she ever tasted. The postage on the Grimes was about 2 cts. on each apple; the Delicious, on account of its size, about 3 cts.

Bradentown, Fla., Dec. 17.

A. I. ROOT.

* Mrs. Root came to me later with a slice of raw cassava and a sprinkling of salt, and she said she was surprised to find it so good.

† After giving the ducks all they wanted we got 9 eggs from 12 ducks next morning.

‡ If I am not mistaken it has been claimed our Ohio hills produce *better-flavored apples* than any of the fancy apples from the far West.

A REAL "DUTCH CHEESE" FROM A REAL "DUTCH FARMER."

I am sure the following will be read with much interest, especially as it comes from a point so near the seat of war:

Mr. A. I. Root:—Your dasheen bulbs came July 22. I am sorry to say that the most of them were rotted. The rest I planted, but they are rotten also in the ground. Notwithstanding this, I thank you very much for your kindly deed, and I am sending to you with this letter a real Dutch cheese, a so-called Edam cheese. I hope you may receive this cheese in good order. I read in GLEANINGS that you like cheese very much, and

therefore I wanted you to have a real "Dutch cheese."

We have here in the Old World a bad time; yet Holland is at this time neutral. My wife is gathering gifts here in our village for the poor Belgian children and women who are leaving their country and coming to Holland to save their lives.

I send you a small portrait of myself in order that you may see if I am a real "Dutch farmer."

Oosterleek, Netherlands, Oct. 5. P. BALK.

It would seem from the above that it is rather uncertain about getting dasheen bulbs to stand so long a trip. The cheese, however, came to hand by mail in perfect order; and if it were not for the fact that *Mrs. Root* objects, I think I should say it is "the nicest cheese I ever tasted." I do not believe we make any thing equal to it here in America, and I fear we do not often get from the old country any thing equal to this sample. May God bless the good wife and all other good wives, wherever they live, in their efforts to give at least a little help to the poor suffering Belgian women and children

SWEET CLOVER, AND WHAT IT IS DOING FOR A MOUNTAIN-RANCH FARMER.

We clip the following from the *Country Gentleman* of December 26, 1914:

On a farm at the foot of a mountain one must expect to find some rough land. Rush has forty acres to be so classed. It is sharply sloping land, somewhat rocky, cut by gullies, and, in spite of all his efforts, overlaid after freshets with rocky streaks. He determined to put this stretch into alfalfa.

Being ignorant of bacterial re-enforcement of his seed he did not secure a good stand. His alfalfa plants were individually strong enough, but they were far apart in location and endowed with a perversity to creep along on the ground. They did well enough for limited pasturage, but furnished not even one cutting of hay.

"The spring following planting I discovered in the middle of my alfalfa patch a strange growth," he told me. "I did not know what it was. I did not know whence it came. It looked like alfalfa, although of rounder leaf and a lighter green. The seed, I concluded, had smuggled itself into my pur-

chased bag. The plant throve when the alfalfa all about it was blighted or afflicted with the 'yellows.' I determined to let it grow. I would see what would come of it.

"The next year quite a patch of this plant appeared in my field. This was a very dry year, but this patch remained green the year through. I decided to have the plant classified for me. 'Sweet clover!' I knew of the existence of such a pest. I was for rooting it out, smiting it hip and thigh. But I observed that my saddle pony was not above eating it. I did not have any very high opinion of that animal. I did not care particularly what became of him. If he was poisoned or bloated by the sweet clover I was prepared to take the affliction with equanimity.

"He throve on it. He preferred it even to alfalfa. This gave me an idea. Perhaps I could teach my other animals to like it. I succeeded. The sweet clover covered the patch of forty acres. As you see, I have so much of it that I can hardly keep it cut and stacked. It makes excellent pasturage and good hay. I cut and cure it precisely as one would deal with alfalfa. I do not have to irrigate it. Thus I save for other things what water I have. It holds

my soil from washing away. It appears to thrive best of all among the rocks that have tumbled down the mountain-side.

"To me the best thing about it is its action on alfalfa and alfalfa's reaction on it. Sweet clover strengthens alfalfa. It prepares the ground for alfalfa. In a pasture made up of about equal parts of sweet clover and alfalfa one may safely let his cows and sheep roam. The coumarin in the clover prevents bloating by the alfalfa. Moreover, when I was teaching my stock to eat the clover I fed the alfalfa with it. They would devour the alfalfa greedily, of course, and now and again would come upon a bunch of the clover. Thus they acquired the taste. Now they will sometimes thrust aside the alfalfa to get at the clover.

"And I have discovered another thing: If one has a good stand of alfalfa, that is just the chance for one to get a good stand of sweet clover. The one inoculates the other. The reverse is true as well. One may secure a good stand of alfalfa on a field where sweet clover has grown even sparsely. This despised plant thus became to me a blessing. Again I learned the benefit to a farmer of just making the best of the thing nearest at hand."

TEMPERANCE

"THE CASE AGAINST THE LITTLE WHITE SLAYER," THE AMERICAN TOBACCO CO., ETC.

I presume every one who reads knows somewhat of the stand Edison and Ford* have taken in regard to the use of cigarettes among their employees; and perhaps many have also seen what the American Tobacco Co. has said in defense of cigarettes. The matter has called up so much interest that Mr. Ford has sent out a pamphlet of toward 40 pages from which I make the following extracts:

MR. EDISON'S LETTER

FROM THE LABORATORY OF THOMAS A. EDISON,
ORANGE, N. J., APRIL 26, 1914.

Friend Ford:—The injurious agent in cigarettes comes principally from the burning paper wrapper. The substance thereby formed is called "acrolein." It has a violent action on the nerve centers, producing degeneration of the cells of the brain, which is quite rapid among boys. Unlike most narcotics this degeneration is permanent and uncontrollable. I employ no person who smokes cigarettes.

THOS. A. EDISON.

Below we give part of a paragraph from a long letter from the president of the American Tobacco Co.:

Unquestionably the cigarette is the favorite smoke of doctors in every city and large town throughout the country. Preachers, lawyers, bankers, business men, laboring men, and men of all classes have deliberately turned from cigar and pipe to the cigarette. Inasmuch as ten to twelve million American men use cigarettes, and perhaps even a larger percentage of Europeans, your charge of feeble-mindedness lies against an overwhelming proportion of the commercial, professional, artistic, musical, and industrial world.

* Henry Ford now occupies the unique position of being at the head of the largest manufacturing institution of any kind in the world. What a wonderful opportunity he has for philanthropic and reform work of this very kind! We may be thankful that he is the kind of man that he apparently is.

May God help the people, especially the boys, who belong to or even *attend* a church where the *minister* uses cigarettes. Does any one know of such a minister? I fear it may be true of some *doctors* and perhaps lawyers; but I am sure, if so, they are already beginning to see what this age demands of a medical and legal adviser.

Below is a part of the reply to the American Tobacco Co.:

I also call your attention to the statement of one of the magistrates in your city (New York) who states that 99 per cent of the boys between the ages of 10 and 17 who come before him charged with crime have their fingers disfigured by cigarette stains.

If, as your letter indicates, scientists and others have thus far failed to find any injurious element in the cigarette, then we must laud Mr. Edison for being the first man to find the reason for the degenerative effect of cigarette-smoking.

I doubt very much the statement you make in your letter that the popularity of the cigarette is possible only because millions of American men have convinced themselves that cigarettes are good for them, and would, therefore, ask you to point out what beneficial result has ever been experienced by any one through indulgence in this habit.

It would appear that the statements contained in your letter are not of such a nature as to be for the benefit and uplift of our wayward lads; and in justice to the American youth who knows not what permanent injury accompanies this habit, this growing evil should be combated.

E. G. LIEBOLD,
Secretary to Henry Ford.

Perhaps I should mention here that, during the past summer, Prof. Wiley spoke at our Medina Chautauqua. Well, after his talk it was the privilege of the Root Co. to entertain him a couple of hours or more. I had a long talk with him about medical frauds of all kinds, water-witching, etc. I mention this as some our readers have

suggested that may be I was not in touch or up to date in regard to all new inventions, discoveries, etc., all the while coming out. And let me also mention right here that Dr. Wiley said the American Medical Association (from whom I have so often quoted in exposing harmful so-called "medicines") is the best and wisest authority in our land.

Here is what the Ford people say of Dr. Wiley:

When Dr. Harvey W. Wiley was chief of the Federal Bureau of Chemistry at Washington he had impure food and drug manufacturers on the run all the time. He is unquestionably the leading health and food authority in the United States to-day. Would you know his opinion of the cigarette?

Here is what Dr. Wiley says of cigarettes:

"I commend Mr. Ford, Mr. Edison, and all people who join them in efforts to curtail or restrict, obliterate, or destroy the pernicious habit of cigarette-smoking. The use of cigarettes is making inroads on the strength of the nerves of all who smoke them, especially boys of tender years, or women who smoke them because they think that the practice is smart. The effect may not be so bad on people of more mature years; but not in any case, no matter how old a man or woman, is smoking helpful. Besides constituting a nuisance, the financial strain connected with use of tobacco stands between millions of people and home comforts."

Below are some more from the best authorities of the present age.

CONNIE MACK SPEAKS.

The boy who does not know of Connie Mack is not old enough to read the newspapers and take an interest in baseball. As leader of the Philadelphia Athletics, Connie Mack takes rank as one of the greatest generals baseball has ever known. He reads men and boys as an ordinary person reads a book. He contributes to the *Scientific Temperance Journal* this characteristically clear statement:

"It is my candid opinion, and I have watched very closely the last twelve years or more, that boys at the age of ten to fifteen who have continued smoking cigarettes do not as a rule amount to anything. They are unfitted in every way for any kind of work where brains are needed. No boy or man can expect to succeed in this world to a high position and continue the use of cigarettes."

CIGARETTE IS ONE OF THE WORST HABITS.

Hon. Benjamin B. Lindsay is judge of the Juvenile Court in Denver, Colorado, where are handled the cases of boys and girls who have gone wrong. He is often referred to as "the golden-rule judge" because of his kindness, and the deep interest he takes in boys and girls. In telling "What I Have Seen of Cigarettes," Judge Lindsay says in part:

"One of the very worst habits of boyhood is the cigarette habit. This has long been recognized by all the judges of the courts who deal with young criminals, and especially by judges of police courts, before whom pass thousands of men every year who are addicted to intemperate habits. These judges know that in nearly every case the drunken sots who appear before them, a disgrace to their parents, themselves, and the State, began as boys smoking cigarettes. One bad habit led to another. The nicotine and poison in the cigarette created an appetite for alcoholic drink. The cigarette habit not only had a grip upon them in boyhood, but it invited all the other demons of habit to come in and add to the degradation that the cigarette began."

HUDSON MAXIM ON THE CIGARETTE.

Hudson Maxim has won world renown as the inventor of high explosives for use in battleship guns and torpedoes and for various other purposes. He comes out squarely against the cigarette in this fashion:

"The wreath of cigarette smoke which curls about the head of the growing lad holds his brain in an iron grip which prevents it from growing and his mind from developing just as surely as the iron shoe does the foot of the Chinese girl.

"In the terrible struggle for survival against the deadly cigarette smoke, development and growth are sacrificed by nature, which in the fight for very life itself must yield up every vital luxury such as healthy body growth and growth of brain and mind.

"If all boys could be made to know that with every breath of cigarette smoke they inhale imbecility and exhale manhood; that they are tapping their arteries as surely and letting their life's blood out as truly as though their veins and arteries were severed, and that the cigarette is a maker of invalids, criminals, and fools—not men—it ought to deter them some. The yellow finger stain is an emblem of deeper degradation and enslavement than the ball and chain."

In closing let me call attention to the self-evident fact that the Tobacco Co., like the brewers and distillers, has no object in life, no motive for living, other than to "make money, more money," while our good men and women are, with scarcely a thought of self, giving their lives for the uplifting of humanity, especially our growing boys and girls.

"RENDERS INFERIOR SERVICE."

That is what the great railroad company, the Baltimore and Ohio, says of its employees who use tobacco while at work. See below, taken from *Medina Gazette*:

The B. & O. R. R. Co. has placed the use of tobacco by station employes and others who come in contact with the public under ban during working hours. The railroad company does not seek to restrict the use of tobacco by its employes when off duty. But it is believed by the management that a man using tobacco while at work renders inferior service, to say the least; and aside from the time lost in "lighting up" there is a certain class of people to whom exhaled tobacco smoke is objectionable.

Another great railway company has said: "No employe need expect promotion who uses tobacco while at work."

"TAGGING THE SOULS OF MEN FOR PERDITION."

The Bradentown *Evening Journal* says:

Dispatches announce the fact that a Columbus, Ohio, brewery, a twelve-million-dollar corporation, went into the hands of receivers of the Federal Court. The dispatch carried the laconic statement: "The decreased beer demand and the adverse legislation in many dry States is given as the cause."

It scarcely would be becoming in citizens who manifest a pride in the industrial development of the country to rejoice in the failure of an enterprise of large proportions which is engaged in its legitimate work of tagging the souls of men for perdition; but those who look hopefully forward to the time when this shall be a saloonless nation cannot but note with satisfaction that the liquor business is growing less alluring year by year.

Gleanings in Bee Culture

Planet Jr. Seeders and Cultivators

Planet Jr tools are the greatest time-, labor-, and money-savers ever invented for the farm and garden. They pay for themselves in a single season in bigger better crops, and last a lifetime.

Fully guaranteed.

No. 25 Planet Jr Combined
Hill and Drill Seeder,
Double Wheel Hoe,
Cultivator and
Plow

A splendid combination for the family garden, onion grower, or large gardener. Is a perfect seeder, and combined double and single wheel-hoe. Unbreakable steel frame. Capacity—2 acres a day.

No. 16 Planet Jr Single
Wheel Hoe, Cultivat-
or, Rake and Plow

The highest type of Single Wheel Hoe made. Light, but strong, and can be used by man, woman or boy. Will do all the cultivation in your garden in the easiest, quickest, and best way. Indestructible steel frame.

Planet Jr 12-tooth
Harrow, Cultivator
and Pulverizer

Stronger, steadier in action, and cultivates more thoroughly than any other harrow made. Non-clogging steel wheel. Invaluable to the market-gardener, trucker, tobacco, or small-fruit grower.

72-PAGE CATALOG (168 illustrations) FREE.

Describes 55 tools, including Seeders, Wheel Hoes, Horse Hoes, Harrows, Orchard- and Beet-Cultivators. WRITE POSTAL FOR IT.

EDITORIALS

Our Cover Picture

THIS is the promised special number on personal experiences of prominent beekeepers. How do you like it? Do you not think that the beginners of 30 or 40 years ago had a harder time than do beginners of the present day now that all these early mistakes have been pointed out?

Our cover picture shows an apiary of one of our younger prominent beekeepers, Mr. Ira D. Bartlett, of East Jordan, Mich. Another view of this same apiary appears on page 101.

Date of the Pennsylvania Convention Changed

THE annual meeting of the Pennsylvania State Beekeepers' Association will be held in Harrisburg on the afternoon and evening of Tuesday, February 23, and forenoon and afternoon of the 24th, instead of Friday and Saturday, February 26 and 27, as announced in GLEANINGS for January 15. The dates have been changed so that beekeepers in attendance can more readily see their representatives in regard to proposed legislation. A full announcement will be found under head of Convention Notices.

Gleanings for 1915 Worth Reading

THE readers' attention is called to the fact that these columns will contain reports of valuable experiments in wintering and increasing bees at the Dismal Swamp, Virginia. We intend to give the unvarnished facts as they occur. Our Apalachicola proposition did not pay expenses, as the final figures now show. Whether the Virginia proposition may turn out any better, we shall see. In the mean time our readers will get the benefit of all these expensive experiments—experiments that the ordinary beekeeper himself cannot afford to make. Where we lose out on these experiments we

shall hope that our readers will stand by us by rolling up a subscription list large enough to enable us to do for them what they cannot do for themselves.

An Anti-spraying Bill for Massachusetts

THE Massachusetts Society of Beekeepers, by Mr. Frank W. Frisbee, President of the society, have prepared a bill to be presented to the Massachusetts General Assembly, to be acted upon during the coming session, regulating the use of poisonous spraying materials upon the foliage of trees and shrubs and vegetation in general, the purpose of the desired legislation being to protect the beekeepers and their allied interests. In order to get this through, beekeepers should write to their senators and representatives at once, urging their support of the measure.

The Ohio State Beekeepers' Convention at Columbus

THIS was held on the State Fairgrounds in connection with the general horticultural exhibit, on Jan. 11 and 12. The afternoon session on the second day was held with the State Horticultural Society, during which the relation of bees to horticulture was discussed.

The meeting of beekeepers was not large, owing, no doubt, to the fact that it was impossible to give a general announcement through the bee-journals, as the secretary and president could not determine the time and place of the convention of the Horticultural Society. But what the convention lacked in attendance it made up in enthusiasm in the discussions. Some arrangements were made for one or two field days, and it is possible that the next convention will be held at Akron—a locality where there are such immense areas of swamp bee-pasturage.

Mr. J. H. Morris, one of the State foul-brood inspectors, was elected for the ensuing year as president; Mr. A. J. Halter, of Akron, vice-president, and Mr. E. R. King, of Athens, re-elected secretary.

Double Telescope Covers vs. Single-board Covers

DURING the sudden cold spells late last fall we had a most excellent opportunity to compare the two styles of covers on bees. The weather turned so very cold that we were not ready to put the bees in the cellar until they had a flight. We replaced some of the single-thickness board covers with double telescoping covers at the home yard. While, of course, the bees had no opportunity to seal down the super covers, it was perfectly evident that the combination was much warmer than the single-thickness cover. The clusters were expanded somewhat, even though the temperature went down in some cases. Next year, for fall work we propose to have thin cushions to put between the outer and inner cover. With such a covering and a chaff division-board, one on each side of the cluster, a colony will be housed almost as warm as in double-walled hives without the bulk or weight; then when settled cold weather does come on we shall have hives that will be ready to put in the cellar, and hives, too, that, when set out in the spring, will protect their colonies much better than if the single thickness of wood all around were the only protection.

The double telescope covers cost a little more; but the experience of the last few days with cold weather shows us that they will more than pay this extra cost in one season. Extreme cold with limited protection will cause the bees to overfeed. Over-eating causes dysentery. While a good flight will clean up the bees it does not repair *all* the damage done. When conditions are right there will be no spotting or black ill-smelling stains.

Upward Absorbents vs. Sealed Covers

It will be remembered we have always argued (for our own locality at least) against absorbents with upward ventilation for colonies wintered outdoors, and in favor of sealed covers, so called, using ordinary super covers that were laid on top of the hives, but not sealed down. Strictly speaking, then, we did not use sealed covers, but an arrangement that was a compromise between the two extremes; and this is the arrangement that at Medina has generally

given us the best results. A board like a super cover is, of course, better than a sheet of glass, as it is a better non-conductor of heat, but it does not permit of easy observation so that the position and size of the cluster can be readily determined. Colonies with absorbing cushions and upward ventilation have a wire screen placed over them upside down, the same as we use in shipping bees by the carload or moving them from yard to yard. Over this is placed a square of burlap, and the whole is covered with loose planer shavings. The wire screen of course enables us to see down into the cluster the same as through the glass.

Mr. Holtermann called our attention to the fact that we had not provided an air-space over the top of the absorbing material, which he regarded as important. This we have remedied, so that the two ideas or two schemes of top packing may be tried out thoroughly side by side in the same winter case.

In the same yards we have also colonies in individual double-walled hives of the usual pattern. These colonies appear to be wintering well. At present at least the scheme of wintering four colonies in one large quadruple winter case looks good.

Careful records are being made, and the result will be published from time to time in these columns.

Hams and Comb Honey; Is there an Unjust Discrimination between the Two on the Part of the Government?

SEVERAL times of late the statement has been made that hams may be sold with their wrappings at so much a pound, wrappings and all. Attention was drawn to the fact that if the container of a ham could be weighed in and sold as so much ham, that comb honey, including the section around it, ought by the same token to be weighed in and sold as so much honey; that it is inconsistent to allow the container to be weighed in one case and of being excluded in the other; that if this was true, the comb-honey business was being unfairly dealt with.

While in Washington lately we took up this question and found that hams—in fact, all kinds of packed meat—come under the jurisdiction of the Bureau of Animal Industry. All other foods and drugs come under the jurisdiction of the Bureau of Chemistry. As the two bureaus are entirely separate, there is no inconsistency in the ruling nor in the interpretation of the law as put out by the Bureau of Chemistry or by the Bureau of Animal Industry.

The suggestion was made that the National Beekeepers' Association should make a test case of this in the courts by shipping some honey, not properly labeled, to a consignee, in some other state. A friendly suit might be entered, and the case argued pro and con on both sides; and when the court renders its decision we would know whether comb honey is a package or not within the meaning of the law. But the probabilities are that the court would rule in accordance with the interpretation made by the Bureau of Chemistry, and, besides, it is doubtful if the National Beekeepers' Association would have the funds to conduct so expensive a suit.

The Editor of Gleanings Visits the Apicultural Building of the Government near Washington, D. C.

ON our return trip from the Dismal Swamp we stopped off in Washington and hunted up Dr. Phillips. In the language of Roosevelt we were simply *delighted* with what we saw, especially in the apicultural building of the Government at Sommerset, a suburb of Washington, D. C. For pictures of this building and grounds see cover for Nov. 15th GLEANINGS and p. 856, Nov. 1.

As announced elsewhere, Dr. Phillips and his assistants are continuing in their new quarters their series of experiments in taking winter observations on the internal temperature of a cluster of bees. In fact, there are several clusters in the cellar and outdoors. Daily records are being taken, including Sundays, and these data are being entered in tables and charts that will doubtless be given out to the public at a later time. It would be premature for us to give any thing at this time, as Dr. Phillips wishes to be sure of his ground before any thing is made public. We may say, however, that he and his assistants are testing out not only different temperatures, but different kinds of foods, particularly candies, and their effect on bees. Further researches are being made into the anatomical structure of bees. Nothing is taken for granted, but every thing is being done with the utmost care and precision.

In the matter of wintering, for example, the beekeepers of the country have been at sea because the ordinary layman is either careless in his method of reporting what he sees or does not actually see what he *thinks* he sees. Too many times the average man jumps at conclusions based on a single observed incident. Dr. Phillips and his assistants are drawing conclusions from scores and scores—yes, we might say thou-

sands—of observations. These data are carefully tabulated and charted, and they will speak for themselves when they are given out to the public.

Our Visit to the Bureau of Chemistry, Washington, D. C.; an Interview with A. S. Mitchell Regarding the Operation and the Interpretation of the National Net-weight Law

MR. A. S. MITCHELL is secretary to the Committee in the Bureau of Chemistry that has to do with the interpretation and operation of the Federal net-weight law. These men, by virtue of their position, are compelled to stand between the public and the manufacturers and sellers of foods and drugs. We explained to Mr. Mitchell that the opinion rendered, that the wood or section around a square of comb honey could not be weighed in with the honey, was raising a big protest among beekeepers. He was very frank to say it was not clear, even to him, that a section of honey was a *bona-fide* package within the meaning of the law; but it was his private opinion and that of his associates that the courts would rule that the wood around a piece of comb honey or what is technically called the section, could not be weighed in. There could be no question, he said, but that a section of honey inside of a carton or wrapper of any sort was a package. He was sorry that the law was causing protest among honey-producers, but he begged to assure us they did not make the law, nor did he go so far as to say that their Committee could in all cases interpret. The final decision would rest with the courts. We ventured the statement that if we follow the recommendation of the Bureau of Chemistry the courts would be very lenient. He assented to this, adding that the courts probably would not impose any penalty on any man or corporation that evidently was trying to do its very best to follow the spirit and intent of the net-weight law.

A question has been raised by some of our subscribers whether a sixty-pound can of honey is a package within the meaning of the law. We put this up to Mr. Mitchell, and he gave it as his opinion that it is a package on account of its uniformity in shape and size; but he advised that both shipper and consignee, on interstate shipments, should have them labeled or marked according to their net weight or volume. In view of the fact that honey varies in specific gravity, and in view of the further

fact that the net-weight law allows us to use either measure or weight, Dr. Phillips suggested that every square can of honey be marked "Not less than five gallons." While most normal honeys when cold will show a net weight of 60 lbs., in these cans, they may run a few pounds less; and for that reason the suggestion to mark the cans by volume rather than by weight is a good one. Some very good honeys run only about 11½ lbs. to 11¾ lbs. to the gallon. If we were to use a label for such square cans, "Not less than 60 lbs. net," it would not be applicable on honey running 11¾ lbs.

Of course beekeepers know or ought to know that a 60-lb. square can will not hold 60 lbs. of honey unless it is *cold*. A five-gallon can will not hold more than 58 lbs. of a normal twelve-pound honey when hot enough to prevent granulation.

There was one point brought out by Mr. Mitchell that every shipper and receiver of honey should bear in mind; and that is, both shipper and consignee must see to it that the honey is properly marked before it is shipped from one state to another.

Let us suppose a case, and already several instances have come to us something like this:

Mr. A, in Iowa, cannot see any good in the net-weight law. He does not believe it is enforceable, and, what is more, he is not going to pay any attention to it. If he wants to ship his honey to another state he is going to do it; but Mr. B, in another state, does believe in the net-weight law, and desires to buy honey of A. A sample is submitted, and Mr. B makes a purchase. Mr. A ships the honey to Mr. B, in New York. A did not mark the honey in accordance with the net-weight law. In the meantime the Government officials seize this honey and condemn it because it is not properly marked, and Mr. Mitchell told us that the Government was going after some of these fellows of the Mr. A class. "But," said Mr. Mitchell, "in this case A will go scot free because B bought the honey of A. A's title to the honey ceases as soon as it gets to his railroad station. A is not liable, but B is. B not only may lose the honey, but be subjected to a fine and possible imprisonment, notwithstanding that he is morally innocent but technically guilty. The only way B can protect himself is to compel A to deliver the honey f. o. b. to B's freight office. In this transaction the title to the honey does not pass to B until it arrives at his office. In other words, B is not in this case the owner of the shipment. In most cases doubtless, buyers will have all their honey

sent to them f. o. b. their office. In some cases it will not be possible to determine what the freight will be; but the buyer will pay the freight and deduct the same in his settlement for the honey.

It is very important that shippers of honey, either in car or small lots, comb or extracted, mark the net weight or the measure on the container, on all interstate shipments. We happen to know that there are fellows like Mr. A who are going to get into trouble. The Government is only waiting till every one has a full and fair opportunity to learn the operations of the net-weight law. There is no particular time limit, but the probabilities are that some seizures will be made in the near future.

Our Visit to the Dismal Swamp; the Early Winter in and about Norfolk, Virginia

On the 11th of January we started for the Dismal Swamp, taking along with us our expert queen-breeder, Mr. Mel Pritchard, who wished to look over the situation to see what could be done in queen-rearing in March and April next. The early setting-in of winter in and about Norfolk—much earlier than usual—gave us some uneasy apprehensions as to the condition in which we might find the bees, and our fears on examination were not wholly ungrounded. Several local residents said the winter had set in almost a month earlier than usual; and Mr. Francis Danzenbaker, who has lived for years in that locality, stated that it was the coldest winter he had seen in seven years. Taking it all in all, the Root Co. with their bees bumped up against a cold proposition.

The first carload of bees was shipped down to Virginia the last of October. If we had shipped them a month earlier to get the benefit of a month more of brood-rearing, or if we had had fair colonies instead of nuclei, it would have been better. With feverish haste Mr. Pritchard and ourself went through the colonies. The great majority of them were in fair condition; but some of the weaker ones gave us a little fear as to what the outcome might be, as we found some already dead.

The second carload of bees, placed in another yard a few miles further south, were in very much better condition. All of its colonies were in good condition except a very few, and some of these could be saved by nursing.

We had been told that bees could fly in the Dismal Swamp almost every day, and

that is true during normal winters; but it has been considerably colder this winter.

The fact that bees can fly almost every day brings in an element of danger. While these frequent flights of course eliminate all possibility of dysentery, these same flights have a tendency to wear out the bees; and unless brood-rearing can proceed simultaneously the colony will grow weaker and weaker. This winter cold weather set in early in December; and it was extremely cold during Christmas and the holidays. In the mean time brood-rearing stopped entirely. Mr. Pritchard and ourself were a little worried over the outlook. Finally we called in Mr. Edmunds, an old beekeeper of that locality who has carried on beekeeping in a large way for a number of years. He assured us we need have no apprehension over the smallness of some of the clusters, saying that they would pull through all right.

The main cause of the death of some of the colonies was the early winter and robbing. Constant flying nearly every day weakened some colonies, with the result that the stronger ones were inclined to worry their weaker neighbors. This was aggravated somewhat after feeding had begun. We instructed Mr. Jennings not to do any more feeding, but to contract the entrances. This is very important, said Mr. Edmunds, on account of mice, and to conserve the heat of the hive.

Mr. Pritchard called attention to the fact that the *yellow* bees were not holding their own as well as the darker strains of Italians. The fact became more and more apparent as we bent over the bees. The native Virginia brown bees showed up better yet.

Another thing that we observed was that there was considerable "drifting," as the colonies had been placed in pairs. The numerous flight days would call out the young bees in force. The result was that they would have a tendency to join the entrances of the strongest flyers. Repeatedly we observed that, where there was one colony that was weak, the one next to it in the pair would be quite strong, indicating that the former had contributed to the strength of the latter.

This is one objection to putting hives in pairs in the South. Where we found the strong and the weak ones side by side we simply traded place with the hives, allowing the colonies to equalize themselves during the subsequent flight.

We also observed the importance of top protection. Some colonies had more than others; and it was evident that the latter were the stronger. The two days that we

were there, there were heavy frosts in the morning, and it was easy to see the relative size of the clusters of bees on the tin covers, for the exact size and location of the cluster would be indicated by the melted frost, while the remaining area of the cover would show white crystals. We instructed Mr. Jennings to put pine leaves between the inner and outer cover, as we used on these hives what is known as the "telescope" cover, with a super cover or a thin board beneath.

In a few cases the field mice had crowded the entrance cleats into the hive. They did no particular damage except to riddle the combs at one side of the cluster. All cleats have now been securely fastened, with a further contraction of the entrance.

We asked Mr. Jennings and Mr. Edmunds how long this cold weather might last. The reply was that it might pass off in a day, and stay off, or it might last clear up to the last of February or first of March. We hope that the early setting-in of winter will be followed by an early spring.

The Behavior of that Cluster of Bees Behind Panels of Glass; Freezing Bees

As mentioned on page 49 of our last issue, we have been gone from our office for about ten days. Meanwhile there has been considerable cold weather. On the day of our arrival home, on the 21st, we removed the wooden panel to see how the cluster of bees was coming on. It was getting smaller—very much smaller—and the shell of protecting bees was gone. The cluster was broken and scattered, and the bees seemed to be cold or chilled. The next day they were as still as death, and we began to wonder whether they would not, under such conditions, assume a state of semi-hibernation. We looked at them intently, but there was very little movement—only a sort of suspended animation—just enough to show that the bees were alive, but somehow they did not look good. We left them, however, without disturbance. The next day they were perfectly motionless, and the day following there was not a tremor of any kind. Evidently the bees were chilled through. We took the hive off its pedestal near the window outside, brought it inside, and opened it up. The entire cluster seemed to be stone dead. We picked up a few, and warmed them with the breath, but they showed no signs of life. We placed the hive on a hot radiator, and at the same time we removed the cushion so that the warmth of the room could descend into the

hive. For over an hour there seemed to be no sign of life. In about three hours they began to "come to."

There, we have just taken another look. The bees are active again; but they do not look quite normal—in fact, a little logy—and there is a distinct smell of dysentery. We said the bees are all alive, but there is quite a pile of them yet on the bottom-board. A few of them that dropped down from the cluster are beginning to show signs of life.

For three whole days this little cluster of bees was chilled clear through, without any apparent movement. How much longer they might have remained and revived can only be guessed; but it is apparent that, when the surrounding temperature is cold (below freezing), and the cluster is too small to generate heat by muscular activity as shown on page 49, the bees have to remain chilled until the weather changes.

At the time we removed the colony from its pedestal on the outside the thermometer in the hive but remote from the cluster showed 29; and the cluster at the time we examined it in its chilled state was as cold as death. Apparently the temperature of the individual bees in the cluster was the same as the reading of the thermometer—that is, 29.

Some years ago, late one fall, the outdoor bees had a beautiful flight. They rushed out in a roar. A sudden cold wind set in with a rainstorm, striking down to the ground thousands of bees. It began to freeze, and a thin skim of ice covered the bees. We supposed, of course, all were lost, for the cold spell lasted for about three days. Then bright sunshine came on and melted this thin skim of ice. The atmosphere turned warm, when, wonderful to relate, those bees that had been covered with ice began to show signs of life. They soon began to crawl, and after a little they flew back to their hives. Our apiarist told us what was taking place, but we thought he certainly must be mistaken. Examination showed that the bees were rapidly taking wing from the ground where they had been under the ice for three days. Other persons have since reported the same thing.

It is apparent, then, that bees can stand a freezing temperature for a time. Whether they are the worse for the experience afterward we are unable to say.

Again, we have observed over and over again, that, when there is a protracted zero spell for ten days or longer, we find, as soon as it warms up, a large number of the clusters of bees outdoors chilled through

stone dead beyond recovery; that if the zero spell lasts four or five days, or not more than a week, these clusters that were chilled through will gradually assume their normal condition again as soon as it warms up; but if it lasts ten days or longer these small clusters never revive. Apparently, bees can stand a chilling of about ten days, and that is all.

Another fact is interesting in this connection. A few years ago when Dr. E. F. Phillips was at our Medina yard conducting some experiments of his own, acting under his directions we put some queen-cages containing some bees and queens on cakes of ice in a refrigerator. The cages were placed face down on the ice. Both the queens and their attendants were chilled through; and while their temperature probably was not below 34 or 35, they to all intents and purposes appeared dead. We found we could keep them in this chilled condition for about ten days but not any longer. Queens subjected to this long chilling period, contrary to all expectations, began laying normally as before.

We are presenting these observations on the matter of chilled bees during winter to stimulate further observation and get further reports. Dr. Phillips and Mr. Demuth, of the United States Department of Agriculture, have shown that when the temperature of the cluster and the atmosphere immediately surrounding it drops below 57 F. that bees have the power to raise the internal temperature by exercise. They are now trying to determine what amount of protection, if any, is needed to keep the bees as nearly in a state of quiet as possible, so they will not have to "exercise," warm themselves up, overeat, and thus bring on dysentery.

There is a wide unexplored field in this matter of wintering. As will be seen by reports elsewhere, Dr. Phillips and Mr. Demuth are working at this problem from several different angles. Our own experiments as recorded above were for the purpose of confirming their observations already reported on the internal temperature of a cluster of bees.

HIBERNATION OR WHAT?

One more question: Do bees semi-hibernate when they are chilled through so as to preclude movement? Is it true hibernation for the time being, or what? If they could remain in this chilled condition through the winter, or until warm weather comes on, like flies and ants, it would be true hibernation. Again, is it possible that bees under some conditions can remain chilled more than ten days or two weeks?

Dr. C. C. Miller

STRAY STRAWS

Marengo, Ill.

THE WET OR DRY issue is the chief factor in the election of a speaker in the Illinois legislature, and it's which and t'other who wins. "The world do move."

THAT earload of beekeepers from Chicago to Denver makes me feel homesick that I can't go. What a glorious time those Colorado fellows gave us when the National convention was at Denver before!

"IF we are all successful in producing a crop of honey each year, we should fail from overproduction," says P. C. Chadwick, p. 53. May be, m-a-y be. But so long as the average isn't more than 20 cents' worth of honey per capita we'll have to overproduce a big lot before there will be any honey to throw away.

"THE eight-frame is not worthy of mentioning as a beehive. It may do for a home for a nucleus for a short time," p. 36. Don't be too hard on us eight-framers, friend Janes. I humbly concede that a larger hive may be better; yet with the eight-frame I get crops that don't exactly look like the work of nuclei.

QUADRUPLE winter cases are getting such a boom now that it might be worth while to try them two deep, eight in a case, as I saw them at Jesse Oatman's many years ago. [Dr. E. F. Phillips, or, rather, his brother, is trying out precisely this thing. Perhaps we can get them to report on it next spring.—Ed.]

J. G. BROWN, your testimony in favor of the Alexander plan of increase, p. 27, is excellent, but beside the mark. Of course, the plan of increase is good: but please give us names of those who have increased by that or any other plan so that "*you can have two good strong colonies in place of one ready to commence work on your clover harvest.*"

W. L. ROBERTS warns against rearing queens in an upper story over an excluder, as too much trouble and perhaps loss. I don't find it so here. Several times I've had queens thus reared and fertilized when there was no intention on my part to have them reared, and it was all gain. But when I deliberately put brood there for the express purpose of rearing a queen, it's a failure. I wish I knew why.

R. F. HOLTERMANN, p. 56, says with the straight rows of hives facing the same way

the general result is drifting. My bees are that way, and for years there was drifting bad. For years there has been none. Let me tell again what I think prevents it. As soon as a hive is placed on the stand and dead bees cleaned out, the entrance is closed down to an inch square or less. That's all—no drifting. [See editorials.—Ed.]

"EVEN if Dr. Miller has a continuous flow during the spring, surely he must be very exceptionally favored if he has not adverse weather at times when stimulation would be an advantage," says R. F. Holtermann, p. 12. I don't have a continuous flow, friend Holtermann, and I suspect I have as much adverse weather as you. But it isn't so bad as to prevent the queen laying right along; and the chief effect of feeding in adverse weather would be to make the bees fly out to their hurt.

My son gave me a vest-pocket flashlight for Christmas. I had a sort of dark lantern before that I thought fine for looking into hives in cellar; but the flashlight beats it a mile, just as you find it in Medina. Nice, too, to see the time of night. [These little flashlights are extremely handy; fine for looking down children's throats to see if there are any white patches indicating serious trouble. They are also very convenient for running around buildings or barns on a dark night; but the light must not be kept on continuously, otherwise the batteries will soon wear out. The kind that we are using with such satisfaction very much resemble a good-sized fountain pen with a clip to hold it in the pocket. It is 5 inches long and $\frac{3}{4}$ inch in diameter, and costs \$1.00. Extra batteries are 25 cents each.—Ed.]

GEO. W. YORK, formerly editor of *American Bee Journal*, is now a member of the Idaho legislature, where he is likely to get in some good licks for beekeepers and prohibition. The governor is also strong for prohibition. [Yes, and he is in the legislature at the right time. A member has introduced a bill prohibiting the keeping of any bees within one hundred yards of the line of the other property. While we do not believe it can get beyond committee, we can't afford to take chances. All our subscribers who see this should write at once to Hon. Geo. W. York, General Assembly, Boise City, Idaho, offering their protest to House Bill No. 18.]

Later: This has been killed 11 to 47; thanks to Mr. York.

BEEKEEPING IN CALIFORNIA

P. C. Chadwick, Redlands, Cal.

A young queen is half the battle, both in fighting disease and in securing surplus.

If bees are in good condition, and have plenty of stores, they should not be disturbed much during the winter months.

With a light crop of oranges, and with trees in a prosperous condition, the prospects were never better for an abundance of bloom this spring.

The best way to build up weak colonies in the spring is to see that they have a young queen and plenty of stores in the fall. It is the best insurance you can take on bees.

There is no profit in extracting too close, then running for increase every second year. Leave plenty of honey always. Use the time you would spend in making increase in running the extractor for profit.

B. G. Burdick, of Redlands, Cal., expects to leave soon for the Antelope Valley, where he will enter the bee business on a large scale. Alfalfa is the principal source of honey in that section, and the quality is said to be of the finest.

Several apiaries of 200 colonies each can be run by two men with a power extractor by going from yard to yard. But one man to every yard during the honey-flow is worth more than his hire to requeen and to look after details of the yard, and the power extractor can be used to advantage at times also.

Up to Jan. 12 we have had a series of small storms with a light precipitation which has not penetrated the soil to any great depth. The surface has received enough to keep vegetation in a prosperous condition, and prospects for early pollen were never better. More rain, however, will be necessary to produce a crop from wild flora.

J. Edgar Ross, of Brawley, Imperial Co., is disposing of his bees after some years of successful operation. He has become the chief pen-pusher as well as owner of a new newspaper which has already seen issue.

We regret the loss of Mr. Ross from our ranks, but wish him a full measure of success in his new venture.

Within a few years sage honey will become the most desirable of all honeys, and will sell at a premium. The sage ranges are yielding more rapidly at present to brush fires than to the plow. Many of our finest ranges have suffered in the last few years. One side of the famous Mendleson range in Ventura Co. was destroyed last year.

J. Edgar Ross, of Imperial Valley, says the only apiary he has producing alfalfa honey exclusively sometimes produces a white honey. This is the first time I have had an admission that alfalfa produced any thing but a dark honey in Imperial Valley. He also says there are sources of production other than alfalfa that are factors in honey production, which do not produce a light honey.

On Jan. 10 I opened two hives to observe their condition—one an average colony, and the other the weakest in my little home yard. The average colony had four frames of brood and a force of bees sufficient to begin on a full-fledged honey-flow. The weaker one, which is fully as strong as my strongest one last season, had brood in three frames a part of the way across the frame. There has not been a day during the entire winter when these hives have not contained brood. With this condition prevailing at the present time, it looks favorable for a spring working force of bees in this section equal to any of the past ten years.

A gentleman at the State convention spoke of antiquated methods, among which he mentioned the solar wax-extractor. I flinched just a bit, for I am a little tender on that subject. I am just antiquated enough to believe that capping-melters now in general use color the honey. To my mind there is no question about it. If one were extracting a dark grade of honey it might not make much difference; but when a light grade is being handled, and the object is to place it on the market as white as possible, I will take no risks with a capping-melter which runs the honey over a hot metal surface. This of itself has a tendency to discolor. Until I am convinced that it does not discolor, antiquated or not, I will call "old Sol" to my assistance.

NOTES FROM CANADA

J. L. Byer, Markham, Ontario

Jan. 8.—The weather is quite mild, but not warm enough for the bees to fly. Here's hoping we shall get warmer weather before it is colder again. Anyway, the "January thaw" hoped for in my last

Notes has arrived; but in view of the fact that the "oldest inhabitant" says he has seen hundreds of Januarys without once missing a thaw, how could we expect anything else in January, 1915?

Last season a number of queens received in one mail showed signs and "smells" of dysentery in the mailing-cages. At the time, I wondered if bees too young had been placed with the queen for attendants; but since reading the editorial, page 4, Jan. 1, have we reason to believe that boiled honey was responsible? It is an important question, and one in which commercial queen-rearers will be particularly interested, especially in cases where long-distance shipment is necessary.

Quite often we hear it said that, north of a certain latitude, outdoor wintering is not safe, whereas other factors enter into this problem that have to be taken into consideration as much as latitude or weather, which, after all, are what are usually considered in a question of this kind. Here in York Co., Ontario, the winter weather is not nearly as severe as it is in the northern part of Simcoe Co., one hundred miles north, where we have a large apiary. In both cases we winter outdoors; and, strange as it may seem on the mere assertion of the fact, the bees up there are warmer in a forty-below snap than they are here at 10 below zero or thereabouts. The reason? Simply because, as a rule, we have a light snowfall here in York Co., and the hives are generally exposed to all the cold wintry blasts during most of the winter season. Up north the snowfall is heavy, and generally comes early in winter—in fact, it is a rare thing that there is much frost in the ground in that section, while here it will penetrate two and three feet. At this date there is practically no snow in York Co. At the north yard the whole apiary has been about completely covered for two weeks or more. If there is danger that this snow may have a bad effect we have yet to observe it. Two years ago I went up there on New Year's day and found all the winter cases about out of sight—many of them totally covered over. I dug down in front of a few, and in each case

there was an opening melted around the entrances, varying from the size of my hat to a space as large as a half-bushel. I decided they were all right, and found out in the spring that such was the case, as the bees wintered finely and were very strong early in the season. But after the bees have had a cleansing flight in early March or thereabouts, then it is a dangerous practice to leave snow all over hives, because after strong colonies have had a flight, and are breeding heavily, there is pretty sure to be trouble if they are left covered over very long in early spring weather.

VIGOROUS ITALIAN BLOOD IMMUNE TO EUROPEAN FOUL BROOD.

Dr. Millér wonders if I really mean what is implied in the quotation he takes from a recent item of mine in GLEANINGS, page 836, Nov. 1. "Universal requeening with good Italian stock seems to be the only remedy for it." European foul brood is the subject under discussion. Frankly, doctor, that is what I mean; and after wading through all the government literature we have on the subject, taking into consideration the advice of our friends in charge of the department of apiculture, and in various other ways, summing up the evidence of those fighting the plague at first hand, that is the only thing that seems worth doing. True, there are different methods and seasons of doing this requeening; but the evidence seems to point strongly to the fact that where apiaries are all pure Italian stock of a good strain, the disease makes little headway to need curing. Needless to tell the doctor that what I do not know about European foul brood would fill volumes of GLEANINGS, while what I do know might be condensed into a short paragraph. One thing that I do know is that I dread to see the disease make an appearance in my apiaries (none there yet that I know of), while on the other hand I have little fear of our old enemy American foul brood. Possibly it is a case of familiarity breeding contempt; but the fact is that the old-time foul brood is easily diagnosed when once known by a beekeeper; and while destructive if let go, yet we know the course of the disease, how to treat it, etc., while on the other hand this new enemy is very erratic in many ways, and I am tempted to think that even our experts have a lot yet to learn about its various phases as to methods of infection, etc.

BEEKEEPING AMONG THE ROCKIES

Wesley Foster, Boulder, Colorado.

I mentioned in a former issue that bees should winter well. This is rather too optimistic a view, although the winter so far has been very favorable. The bees throughout the state did not breed very well in the fall. Some are

rather short of stores; and in Boulder Co. the honey from the horsemint has apparently not helped wintering conditions in the least. The loss in some districts is likely to run up to 25 per cent. I expect a loss of 15 per cent any way.

The beekeepers of Colorado are going to turn out in force for the National convention. The committees working on local arrangements are meeting with gratifying success. When you come to Denver you will be surprised at the size, enthusiasm, and hospitality of this convention. You will be met at Union station by autos and taken to convention headquarters in the Auditorium Hotel. You will be greeted by specialists, amateurs, and enthusiasts alike. You will be banqueted, lunched, and entertained. You will gain ideas worth dollars, gauged either in hundreds or thousands according to the size of your beekeeping operations.

SUGAR BEETS AND SUGAR.

The editor says on p. 965, Dec. 15, 1914, that sugar is almost sure to remain high in price. This will doubtless be the case; but he goes on to say that there will be no beet sugar raised for two or three years. As Colorado is the largest producer of beet sugar of any of the states, I think that statement is entirely too strong. The sugar companies are making plans for this year, any way, and the farmers seem to be far more exercised over a desire for a higher price for their beets than from a fear for lack of seed. I understand that there is seed enough on hand for this year already for planting.

NET-WEIGHT STAMP FOR SECTION HONEY.

A rubber stamp, much more attractive for stamping comb honey, can be made by having the lettering placed within an oval border. The words "Net weight not less than" should run around the inner border at the top, the weight in ounces spelled out, running through the center, and the bee-

keeper's name and address or number around the lower side of the oval border. I have seen stamps made on this design, and they are a great improvement over the ordinary stamp now in use.

THE ALEXANDER PLAN OF INCREASE.

It is not always safe for a man as young as I am to call in question statements made by a man of the experience of Dr. Miller; but I cannot refrain from protesting the accuracy of his statements regarding the Alexander plan of increase.

I will not trespass on Dr. Miller's white-clover territory, for he knows more about that than I do; but when he states that he does not believe the surplus crop of honey can be increased in one place in a thousand he invades my territory. If he will make his question to read, "What honey-producer increases his crop of white sweet clover and alfalfa each year by dividing his colonies before the white-honey harvest?" I will give my name as doing it four times out of five; and I will state that I believe seven out of every ten honey-producers of the alfalfa-sweet-clover districts of the Rocky Mountain region who practice the Alexander method or modification of it have profitable results. The percentage of successes would be larger if it were not for the fact that so many of our alfalfa locations are destitute of early pollen sources so that it is simply impossible to breed up much until June.

This matter of dividing in early June or late May, according to the season and location, is one of the points that should be pushed among western beekeepers, although they are learning very fast. If increase is not desired, the bees may be united in the fall, and the united colonies wintered in two-story hives.

Dr. Miller has, however, defined the limits of the use of the Alexander plan very well. Here in the West we have an early flow from wild flowers, fruit-bloom, etc., that prepares the bees for swarming in many instances before alfalfa blooms in June. By dividing the force of bees each colony may be steadily built up during June; and in July and August, when the main surplus comes from sweet clover and alfalfa, the two colonies made from one, *a la* Alexander, are both ready to store surplus, and they do too. J. G. Brown has also called in question Dr. Miller's two statements. But then, we are both young men.

CONVERSATIONS WITH DOOLITTLE

At Borodino, New York.

UNITING WEAK COLONIES.

"Last year my bees came out weak in the spring, and many of the colonies died before the honey-flow commenced. By the way things are now looking, I fear I may have the same experience again. How would it do to unite two weaklings, so as to make one good colony?"

There is no doubt that the uniting of two weak colonies to make one strong colony is profitable; still, that uniting must make the one better than either of the two would have been when the honey harvest arrives, or our labor of uniting is worse than useless. We do not hear so much about "spring dwindling" as we did twenty years ago, when often half the colonies in an apiary would be so poor and listless from poor wintering that it seemed almost impossible to get them to build up much before settled warm weather came on, and hundreds of colonies would die during March, April, and May. Then we were told that the time to unite was when it was discovered that any two colonies were too weak to be of use alone. But it was soon found out that, as a rule, the united colony would be no better at the end of a month than each would have been if left separate. In some instances the united colony would perish when two no better than was each of those united would have pulled through and become good colonies in time for the buckwheat flow. Years ago, when I experimented along this line, I put as high as seven such colonies of "worn-out vitality" into one hive, the seven making a rousing colony at the time, and in a month all were dead; while some separate colonies, no stronger than some of the best united, survived and built up for winter.

The trouble seems to be that, where two or more such colonies are put together, the bees feel they are now in condition to do great things, and so work themselves up to great activity in starting a large lot of brood, which wears out what little vitality they have before enough of this brood can emerge to take the place of those wearing out daily, hence all perish; while if they had been left to themselves they would have been less active; the few young bees which emerged would have taken the place of those which died, and, when settled warm weather came, the bees in the hive at that time could care for a large lot of brood in proportion to their numbers, so that the colony would build up for the next winter, if nothing

more. I find in an old diary, that I once had a colony become so weak in this way that there were, by actual count, only 83 bees with the queen on June 10; and yet this little colony, without any assistance from any other colony, built up into a good colony for winter, and gave six sections of nice buckwheat honey. Since then my way has been to confine small colonies to as few combs as they can cover, these combs having plenty of honey in accordance with the number of bees, so that they do not feel any need of scrimping along this line, building them up as fast as possible when it comes warm weather, and then uniting them just before the honey harvest, leaving a nucleus to catch the few bees which may return to the old stand of the weaker of the two which has been placed in the stronger. This will give one colony strong enough for storing, and a nice nucleus to rear two or three good queens from; or if the old queen is left with a comb of honey and the few bees that adhere with her, and these given a frame having a little brood in it, this will build up into a fair colony for winter should the flow prove good from fall flowers.

CONTROLLING DRONES.

"I have six colonies of bees—four blacks and two Italians. Would it be well to give the Italians a comb of drone comb and put drone-traps on the blacks when the young Italian queens are mating?"

If queens are to be mated to Italian drones, of course one must control all drones from undesirable colonies. Drones can be controlled with traps; but we must buy the traps, keep them on the colonies, and furnish the honey necessary to rear and feed the drones, all of which is an expense. Traps would be necessary with box hives; but such are not so much in use these days. For frame hives, much the best way would be to remove all drone comb from the black colonies, and replace it with worker comb. In this way trouble and cost of producing the drones will be saved, as well as the cost of the traps and the disturbance the traps bring to the bees for the first few days after they are put on. Besides this you will rear 50 worker bees to every square inch of such comb you use to replace the drone, instead of the 32 drones, these workers storing honey for you in place of the drones eating it. In any event you could not be sure of having your Italian queens purely mated unless there were no black or hybrid bees within three to five miles.

GENERAL CORRESPONDENCE

BUILDING UP FROM NOTHING

How One Man does Nearly all the Work in Caring for 500 Colonies

BY IRA D. BARTLETT

It is no uncommon thing for me to be asked all sorts of questions about the wonderful busy bee. How long does a bee live? How much honey does a colony make during the season? How many swarms issue from one hive? and then after giving them the best answers I can they will usually tell of the wonders, as they appeared to them, and the miracles performed by old Mr. So and So, when they were boys—how he used to “swarm” swarms without a veil, and with his arms bare, and how the bees would crawl over his face and arms and he never, never got a sting. They had seen the nice yellow wax, and at times *honey*, being carried into the hive by the bees, but it was always on their legs. They had been told the uselessness of the drones, and how the bees did the bidding of the queen.

Regardless of how wrong their ideas were they were interested, though they never investigated further. You and I have seen these same things and heard the same stories. The bright pollen that we thought was honey aroused in us the greater desire to go into the hive and see where it was put, and how things looked in there. We were thrilled by the wonders of nature performed by her agent, the honeybee. Many of the readers of GLEANINGS have just got their first peep

into the hive; and, oh the raptures that thrilled their souls! Some of these beginners will follow beekeeping as a pastime; others will engage in it as their life vocation. The last named are most interested in how the successful apiarist of to-day got his start, and how he increased his colonies and built up his apiaries to where he could make a living from them alone. It would be impossible for me to give here a complete history of my beekeeping life; but I can tell how I advanced.

When I was a boy I lived in town; and whenever there was a chance I hied me to the country, for there were beauty and glories the town could not reveal. I loved nature. I was inspired by the song of the birds, the beauty of the growing crops, the fresh, fragrant, and invigorating breezes, and the grand old sun; and the moon and stars were oftentimes my sole companions. I made the most of my trips to the country where there was a very nice apiary, for I liked honey, and soon I was interested in the bees. Early in May, 1895, the owner of the apiary brought me down a nice prime swarm, for which I paid \$5.00 in labor on the farm. I was a happy boy, and looked into that hive nearly every day. It is a wonder the bees stayed at all; but they did stay until early in August, when out they came, intending to abscond. I hived them, however; and as we had a late fall with good weather, they gathered enough to winter on. The parent colony reared a queen, and I got them both through the winter safely. I at once subscribed for the *American Bee Journal*, and soon after for GLEANINGS, and for two years I believe I read nothing except that which pertained to the bee. I attribute a great deal of my success to

FIG. 1.—Ira D. Bartlett's home, 20 x 40 supply-house, and garage. Mr. Bartlett purchased a Ford touring car in 1914, which he finds is a great saving in time and labor. The residence has full basement, furnace heat, electric lights, bath, etc.

FIG. 2.—Ira D. Bartlett's 160-colony apiary. Another view of this apiary is shown on the cover.

this. The following season I increased to seven; and, although there was no white honey stored, there was a heavy fall flow, and all had plenty for winter. Besides, I extracted 175 lbs. of buckwheat honey from the super on one of the parent colonies.

The extractor I used was a four-frame non-reversible for which I traded a hound pup, giving \$2.00 to boot. This extractor was used until I had nearly 100 colonies.

I wintered my colonies right from the start in winter cases quite similar to what I use now, and was very successful. I started buying colonies from others about me who were not as successful as I, and kept increasing gradually until I had some fifty or so, when I found it to my interest to move them out of town during the summer. I returned the bees in the fall for several seasons, wintering them in father's back yard, and in a neighbor's when father's was full.

Finally I moved for good to twenty acres owned by my father. This ground later became my property, and was my home until a year ago when I moved to town, where I now live.

From the start I got my increase from

natural swarming and the buying of bees, and purchased no queens until a few years ago, when I divided my colonies after the honey-flow in July, and purchased as many queens as I made divisions. I have followed this practice until now, excepting that I tried dividing in June this past season on a few colonies. I must say that I was impressed that this method is ahead of the late division. I made nine increase from two, and had four extracting-supers filled with honey, besides redividing several of the increase the first of August, when I made my regular increase. Doesn't this look better?

I put into winter quarters this fall nearly 500 colonies, wintering 140 in cellars, and the rest in my regular winter hives, which hold four colonies each.

Now, I have been successful as a whole during my beekeeping career; but you must not think that I have not had to work and study and plan. From the start I had to get ahead as best I could. It took money to buy supplies—in fact, for quite a while it took all and even more than I got from the bees from year to year. My father said I spent more than I earned, and so would never

FIG. 3.—One of the outyards. Though situated right in the woods, the bees are never molested.

make any money. I realized this, but hoped to get to a point where I would not have to put it all into the business each year.

I economized by making my supplies in a nearby factory, lumber being very reasonable in price. But I surely would not advise any one who expects ever to have a large number of colonies to make his supplies by hand, for to handle large numbers successfully the hives and fixtures must be made right and of uniform size.

Bees that I purchased I always transferred into my own hives, excepting a lot of 104 purchased in hives of different make but uniform. These were reduced to about thirty, and the other bodies used as supers.

When I purchased bees, supplies, queens, or other necessary equipage, I almost invariably paid cash for them, borrowing the money at the bank if I did not have it. I think this method the most satisfactory to all concerned. In this way I have built up my business quicker, and have been able to accomplish much more and to do it much easier. One thing right here ere I forget: Don't let your business increase faster than your knowledge. Keep posted. Read all the bee-journals, and supply yourself with the best books on the subject.

The past season I managed three apiaries, doing nearly all the work except during the extracting and packing, when I hired one man. I have worked out a system of handling the bees, and find it only a pleasant pastime to handle four or five hundred colonies, and so am planning to increase to 700 the next season if all goes well. I might

mention a few things that I believe are essential to the handling of large numbers with perfect ease:

1. A level ground, or at least a smooth one, with hives systematically arranged for easy access with wheelbarrow.

2. A honey-house perfectly tight with escapes in windows, so that all honey may be brought in at one time, warmed up, and extracted. What a pleasure to work stripped right down, with hardly a bee in the house, all because the supers are rid of bees by the use of

the Porter bee-escape, the bee-escape working well because the brood is all hatched and a wood-wire queen-excluder placed on at the right time! I find it only a short job to put on the excluders or escapes; for after distributing them I have actually put on three a minute where there was only one super.

The reason I can separate the supers so easily is because the supers are uniform and of proper bee-space between. This is due in part to the fact that I clean the top of the frames and take out all burrs just before the first honey comes in. It is not a long job; and, oh the time it saves later! I also clean all extracting frames and supers the same way, using a carpenter's scraper similar to a putty-knife, but wider. The blade is very thin and of steel, and can be purchased for about 60 cents. The scrapings of the supers and hive-bodies will just about pay for labor; so you see it costs nothing, and it is done when you have nothing much to do except to watch the bees build up.

I use the Miller feeder to feed the bees after the crop is taken off. This is very easily done. After reducing the entrance I mix up sugar and water—two parts of sugar and one of water if for late feeding; and after weighing the hives (I guess the weight) I pour in the syrup at evening and the feeding is done. I take off the feeders with escapes after the feed has been taken down and they are ready for winter. I use a steam-heated honey-knife, and the latest Root four-frame hand extractor; but I expect to install a power extractor some day.

I use Root hive-tools, a four-inch copper smoker, and a bee-veil of my own make which I think has every thing to date beaten. This I will describe and illustrate in a later article.

I have not told how I went to work to do any of the things that are essential to success in this business. I know there are scores of little things that will come up that are not explained. I know that many attempting to do some things that I do may not fare just as I have. On the other hand, many have worked out an altogether different system which proves a success. My methods may not do for some other locality; but remember that oftentimes there is some little kink that really makes for the success of the entire system, and the locality is not altogether to blame. It would be impossible for me to try to explain here, step by step, how I proceed from spring to fall.

I am pretty sure I am right in feeding sugar instead of honey, for in this locality I know that sugar won't spread disease, and is a safe winter store. I know that the queen-excluder, properly manipulated, is

not a honey-excluder, and is one of the greatest time-savers known. I know that the escape is indispensable when the excluder is used, and a nuisance when not. I know that a clean level yard is a wonderful help in taking off honey and at other work, and will not ordinarily cause any trouble in getting queens mated. I know, too, that in a well-lighted, commodious, tidily kept honey-house, free of bees, nearly twice the work can be accomplished, and the honey goes into the cans free from dirt or bees, and is really worth more on the market.

Now just a word to the beginners. It is said 90 per cent fail who enter the bee business. You expect to be among the 10 per cent who succeed. Success is a matter not so much of locality as it is of the man. If you are a good, clean, moral young man, full of ginger and ambition, and exercise some judgment, you will succeed in the bee business as in any other line. Don't think that the bees always work while you sleep. Remember that a little vim and push are required, even in this vocation.

East Jordan, Mich.

PERSONAL REACTIONS AND REWARDS

BY J. L. BYER

After receiving the editor's request that I contribute an article to the special number on experiences of prominent beekeepers, it was with reluctance that I finally consented to oblige him in this matter. In the first place, it seems that, after writing more or less steadily for a number of years, the beekeepers will have come to know all about my fads and fallacies without my retelling them; and, again, I rather object to the term "prominent beekeepers," knowing full well that many who have never written a line publicly have nevertheless a greater claim to the title, judging them by their success in the calling. In GLEANINGS, Jan. 1, 1913, an article was published from myself under the heading "Mistakes and Experiences of Beginners," and if I should repeat any thing at the present time that was published then, readers will have to bear with me; for in an article where personal references have to be made it will be impossible to do otherwise.

As all who know me are aware, my apiaries are not pretty to look at, since for the most part they were bought of different people and are, of necessity, in different patterns of hives. In fact, I have every thing from the regular eight-frame L. hive, which I regard as much too small for ex-

tracted-honey production, up to the twelve-frame Quinby, or Jumbo, as some would call it. Having these different kinds of hives is not a matter of choice; but as I started beekeeping with no funds on hand, and no other assets than a good wife and three children, I was no chooser in the matter of kinds of hives, and bought bees in

FIG. 1.—Part of one of J. L. Byer's apiaries in double-walled hives permanently packed.

whatever hives they happened to be. In the course of a few years I cleaned up the various small lots around us, the owners finding the bees unprofitable with the limited attention usually given to such stock by farmers. These few remarks will show that,

FIG. 2.—View looking south from the apiary shown in Fig. 1.

in the main, very little increase was made the first few years I started to keep bees for a living aside from buying the bees outright. At that time I could buy good strong colonies at from \$3.00 to \$5.00 each; and I

and often it is hard to get them at any price. Just a word of caution to prospective purchasers of swarms in localities more favored than ours:

In leaving hives for the bees to be put in, be sure that all the frames are correctly spaced, and fastened securely in some manner; and if foundation is used instead of combs, see that all sheets are well wired. If self-spacing frames are used, the first caution is unnecessary; but in all cases foundation should be well secured. Neglect of these small matters will lead to a lot of trouble, as I found to my sorrow on my first few trials of getting swarms.

From the very first I started one outyard in addition to the bees I placed at home. This apiary already had some bees belonging to my father. This made it necessary to tackle at once the problems incidental to outyard work; and while the methods used to control swarming are beyond the province of this article, yet since the matter of making increase is one of the items season-

FIG. 3.—Corner of one of J. L. Byer's apiaries of 250 colonies; hives single-walled; natural protection afforded by elevation to north, and bush on other sides.

still believe that, for stocking outyards as well as making increase at such out-apiaries, this is still the cheapest plan, provided bees can be bought as cheap as they could be twelve or fourteen years ago. At that time a few beekeepers of my acquaintance allowed much natural swarming, and would often offer me strong first swarms at \$1.00 each. I would take the hives filled with full sheets of foundation; and when bees were in them I would go some night and bring them home. At this time I

FIG. 4.—Same apiary as shown in Fig. 3, packed for winter, two hives in a case, all facing south.

was still on the farm, and working there nearly every day; and many a night have I been on the road till early morning on trips bringing home bees after I had worked hard all day on the farm, and was expected to be ready for duty at 5 A. M. again.

But things have now changed; and instead of buying bees at three or four dollars a colony, or swarms at one dollar, double those prices will be asked,

FIG. 5.—Part of J. L. Byer's apiary shown in Figs. 3 and 4, taken later when covered with snow.

FIG. 6.—Motor boat used at the apiary shown in Figs. 3, 4, and 5.

able at the present time I shall say a few words along that line. The fact is apparent at once, even if we never ran outyards, that natural swarming is not to be considered at all in the matter of making increase at outyards; and as losses are bound to occur there as well as at home yards, we soon had to decide the best way to go about making up these losses. Numerous plans of dividing up the colonies into two or more nuclei were tried for a while, as my grandfather, who was a successful beekeeper, had used this method in my earlier days when I had little thought of keeping bees for a living. But I soon discarded the plan for different reasons, and in the end settled on the nucleus system now commonly in use by a good many. This plan differs from the old-time dividing scheme in that all brood is saved, and the colony from which the increase is being made is not perceptibly weakened or disorganized for the gathering of a crop of honey.

have ordered, go to a colony strong in bees and brood, and, after finding the queen and placing the comb she is on at one side, lift up four frames with brood and place them in the upper story with a queen-excluding zinc between the two stories. Do this with as many colonies as you wish to increase, filling with worker combs or full sheets of wired foundation the empty space in the brood-nest from which the combs of brood were taken. Seven or eight days later, when your queens arrive, go to these colonies and place the four frames of brood with all the adhering bees you can take with them into a hive already prepared. Place this hive on its stand, and at once introduce the young queen to them by any of the well-known methods. As you are dealing with nearly all young bees in the nucleus (any old field bees in the recently formed nucleus will at once fly back to the old stand), introduction will be successful in nearly every case. In fact, I cannot recall having lost a single

queen when introducing to nuclei except in one or two cases when the old queen had got up through the excluder, and had then been carried into the nucleus on the combs of brood. Many would advise using less than four combs; but, all things considered, I prefer that number instead. There is no mistake in making a colony *too* strong; but thousands of mistakes are made by making them *too weak*. In an ordinary season a nucleus made as I have described will build up into a strong colony

FIG. 7.—25 miles from home at 6 A. M., on the banks of a trout-stream.

Luncheon at the Colorado Honey-producers' Association, at the annual meeting, Dec. 29, 1914. Seventy were present. The National meets here Feb. 16, 17, 18, 1915.

for winter without any further fussing aside from filling out the vacant space in the hive with foundation or comb as it is required. This increase should be made only at the time of a honey-flow, and I prefer to have the work done just after clover has started to yield nicely. Drawing brood from very strong colonies often heads off swarming by giving the queen lots of room in the brood-nest just when it is needed; and the honey-storing power of the colony so treated will be reduced very little as compared with other methods which often totally disorganize a colony for a few days at least—often for a much longer time. While this plan is old, I firmly believe that it is the cheapest method yet known, when all the factors are considered, such as labor, depreciation in amount of honey stored by the parent colony, and absence of worry over all methods used in which natural swarming is in any way to be considered.

Some of the most frequent questions asked me are as to methods of wintering practiced, and the kinds of hives I use. The last has already been answered; but I might add that, in so far as personal preferences are concerned, if starting all over again, and I had it in my power to choose any kind of hive I wish, I certainly would take the ten-frame Quinby or Jumbo hive for ex-

tracted-honey production. Not being a comb-honey producer I would not care to give any opinion in that line. But I always advise *beginners* to use the ten-frame L. hive for extracted honey, as it is a standard make, and can be secured at any time from all dealers in bee-supplies.

I have even been asked more than once by letter, "Just how much money have you made in beekeeping?" This question can be answered by a little story I often heard from a well-known character who used to live near us. He used to say, "Canada is a splendid country to get along in. I came from England forty years ago with nothing, and have held my own remarkably well. I have nothing yet." This might be a slight exaggeration in my case, but not so much after all, as I make no claims to accumulating much of this world's goods. Starting with nothing, and raising and educating a family, requires considerable income; but even if very little money has come our way, we have enjoyed the work, and have had enough to eat and wear. What more could be desired, any way? Previous to this year we lived in a rented place; but we have now purchased two acres of land and erected a modest house 28 by 30, having many conveniences, such as hot and cold water in all three stories, with a fully equipped bath-

room—something we have never enjoyed before, and something that is altogether too scarce in homes of many people who can afford such things better than we can.

In regard to wintering, I prefer the permanently packed hive both for winter and summer, and the first cost of such hives is all that would keep me from using them altogether. Two years ago I purchased a camera; and, although the veriest greenhorn in photographic matters, for some reason I have had fair success in its use, and very rarely fail in getting a good negative.

Fig. 1 shows part of one apiary in which the bees are in the kind of hives I prefer—always ready for winter in so far as packing is concerned, except placing a cushion of sawdust on top in November. The location shown is a natural beauty spot. Fig. 2 shows a view from this yard looking south. Fig. 3 shows part of one apiary which has 250 colonies in it. It is needless to say this picture was taken a year ago. We didn't need to pile supers very high in 1914, although this yard was the only one that gave us any surplus at all this year—about 50 lbs. per colony. The yard is sheltered on all sides as shown, with timber on three sides and high rocks on the other. Fig. 4 shows a small corner of this same apiary packed for winter. I do not like the four-hive cases. They are altogether too bulky to handle; and then, again, I like a south entrance. As will be seen, the cases we use here take but two hives each. Fig. 5 shows the same apiary when covered with snow a year ago.

At this date (Jan. 2, 1915) they are covered much deeper than the picture shows. The thermometer goes to 40 below zero here, so I am not worrying about snow over hives. Fig. 6 shows the motor boat we use at that yard. The gentleman at the right is my father, who stays at the yard up there during the summer, my son also being there in the busy season. Fig. 7 shows my youngest lad, my two eldest girls, and a cousin, near a trout stream 25 miles from home at early morn of a summer's day. One of my great weaknesses is a love for fishing—especially fishing for the "speckled beauties," and on the occasion on which the picture was taken the other members of the party were persuaded to go for a picnic so that the pater could have a day off at his beloved sport.

I might yet add, in connection with the boat shown, that it is used to go to town five miles away for groceries, etc. Then it is often used for pleasure as well, as a run down the river to the bay at the close of a day's work is splendid recreation, to say nothing of doing a bit of fishing now and then as occasion offers. It is 24 feet long, and has a twin-cylinder six-horse-power engine, capable of developing about twelve miles an hour. In locations where navigable waters are within reach, this means of locomotion is far ahead of the auto in many respects, especially in economy of first cost, upkeep, and roads. The latter never get "muddy," at least with the boat, even if they are sometimes "rough."

Markham, Ont.

A REMARKABLE START OF A REMARKABLE CAREER

BY DR. C. C. MILLER

When I was a boy I had a bumblebees' nest in a cigar-box up in the haymow. I don't think that had any thing to do with my being a beekeeper. Later I helped my stepfather carry home, one night, a colony of bees in a box hive before the days of movable-frame hives. It was set on top of a "bee-palace," a barn-like affair big enough to hold half a dozen colonies. The expectation was that the bees would build down and fill the "palace," and then the door could be opened and a nice cake of honey cut out whenever desired. But the bees didn't seem to have a full understanding of what was expected of them, and died without building down. I don't remember that I had the slightest interest in the bees or their untimely demise.

Not till I was thirty years old was any interest in bees awakened. That was in 1861, when on a day next to the Fourth of

July a swarm of bees came sailing across Marengo. Seeing them, my wife began to throw water upon them. I don't know how much effect that had, but at any rate she got those bees into a sugar-barrel. I was in Chicago at the time; but when I got home I began at once to be interested in beekeeping. A barrel didn't seem the best lodging for bees, and the next spring I made box hives, Quinby style, and had them occupied. Holes were bored through the top of the hive, and six-pound boxes were placed on top, with a telescope cover over all.

The bees I had at that time were such as probably most of the beekeepers of the present day have never seen—pure, unadulterated blacks. These remained in their purity for five years, when in 1866 I got my first Italian queen. That gave me an opportunity such as cannot easily be had at the present day to know the difference be-

tween blacks and Italians. Whatever may be the case in Switzerland and other lands across the sea, one of the things that I know for certain is that Italians are far and away ahead of the blacks that I had, and I made a good bargain when I paid \$10.00 for an Italian queen.

Some things in which blacks differed from Italians would seem strange to many a beekeeper of to-day. I wonder, for instance, how many of my readers ever saw a good case of "roping down." When a frame covered with blacks was held up by one corner, the bees would run down over one another and string down from the lower corner until they formed a "rope" six or eight inches long. The important difference, however, was the difference in the amount of honey gathered.

In 1863 I had begun to use a movable-frame hive having a frame of odd size, the dimensions of which I do not now remember; but in 1870 I adopted what I supposed was the regular Langstroth hive. In one respect it was more "regular" than the Langstroth, for there were no fractions in the dimensions of the frame. It was 18 x 9, while the Langstroth is $\frac{3}{8}$ inch shorter and $\frac{1}{8}$ inch deeper. That little difference in size seems hardly worth considering, yet when later I came to change to the regular size it cost no small sum in money and trouble.

In 1870 I got a honey-extractor, the Peabody, the best then known. There was no framework revolving in a can, but can and all revolved. A handle was on top, and you leaned over and made it revolve, and you had to be careful when the extractor was in full motion lest the projecting frame should strike fingers or clothing.

In 1871, having bought several colonies at different times, I succeeded in having fifty hives to go into cellar for winter, each hive containing bees, although some of the hives contained scarcely more than nuclei. By the time the season opened in 1872 I had two colonies left! How was that for encouragement after eleven years' work? But as I

was keeping bees only for the fun of it, it didn't trouble me, and I went at it afresh.

But why give in detail all the ups and downs of my career in getting started as a beekeeper? Are they not all duly recorded in the chronicles of my experience in the book "Fifty Years among the Bees"?

In 1877 I returned to comb honey, using pound sections. They were four-piece, there being as yet no one-piece. For 38 seasons I have continued the production of sections; but for the past two years I have extracted some 500 pounds each year. If I were to begin afresh it is quite possible I should extract mostly or altogether, chiefly because it would be doing just so much toward having more honey eaten, and so having a stronger nation!

Although beekeeping was for a long time only a side line, yet as the years went by I began to dream of a time when all my time could be employed in working with bees, planning about them or writing about them. In 1878 that dream became a reality, and I have now passed through 37 seasons as a specialist in beekeeping. And what a good time I've had! Some talk about the enthusiasm of the beginner, and the better results obtained because of that enthusiasm. All fudge—at least in my case. Last summer, my 54th summer with them, I was just as keen in working out new problems with them, and, if you must insist on my telling it, just about as likely to try some fool thing with them that would turn out all wrong, and withal just as grateful to God for the enjoyment of it all, as I was in the middle of the past century.

Young fellow, if you have no other interest in bees than the money to be made out of them, let 'em alone. But if you're so built as to love bees, to think bees, to dream bees, go to it; your chance to-day is better than when I began. And if you want just a word of advice from one who would be glad to begin it all over again, let me advise you to *breed from the best all the time for all your colonies.*

HOW NOT TO DO AND HOW TO DO: BEGINNING IN BEEKEEPING

BY R. F. HOLTERMANN

[The following article is the first of a series by R. F. Holtermann upon the general subject, "How Not to Do and How to Do." The second of the series will be published in an early number.—Ed.]

When one is about to undertake a certain piece of work it is his duty to do that work thoroughly and expeditiously. It should be a fixed principle to expend no more time and energy upon an operation than necessary, for act upon act in time becomes a

habit, and such a habit results in making, to a greater or less extent, success or failure of the work. Let me illustrate, and perhaps I may be pardoned for referring to myself. Many years ago, when times were hard, and I was a young man with but little ready

money, I wanted work for the winter. A friend obtained work for me at 85 cents a day in a factory making bee-supplies and other goods. After paying three dollars a week for my board there was not very much left for other expenses; but I took the job, beginning about Dec. 1. In my work I saw better ways of "doing things"—methods by means of which time could be saved and sometimes better work done. The result was that by spring I secured \$1.50 per day, and worked myself up to a salary of \$1500 a year.

To repeat, it is a waste to spend more time and energy in any operation than necessary. It is not only wasteful at the time, but tends to bad and slipshod habits in work. If one requires the exercise he had better take it with a set of dumbbells or Indian clubs. From observation I should say few bear this in mind when doing their work.

If we survey the horizon of our experience and make an analysis of our contact with our fellow-man, or even examine ourselves, are we not forced to the conclusion that people are a good deal better at telling how not to do things than they are at telling how to do them? True, with criticism the question is not one of the spirit in which it is offered, but is it just and fair—that is, when the subject of criticism is considered? On the other hand, when the critic is considered the question is, "In what spirit do I criticize?" In taking up the subject for the beginner, "How Not to Do and How to Do," I want to point out, in no spirit of fault-finding, the wrong way to do things, as a means to educate and fix wrong methods upon the attention, and then, as far as lies in my power, to give a better method.

HOW NOT TO DO.

There are many things which lead up to making one decide to engage in beekeeping. Sometimes the imagination has run riot with reason; perhaps a sanguine temperament has before the mind's eye a splendid honey season to the exclusion of any of the poor seasons where the profits are nothing, and where the gross receipts are looked upon as net profits. One thing is sure—that no one has any right, if he desires to act in wisdom, in thinking that he can make a living by keeping bees unless he has a practical training in the business. It is true that there are many successful beekeepers who have started in a small way and worked up until their success has warranted them in making beekeeping their main occupation; and what has been done in the past can, no doubt, be done again; but such persons secure their practical knowledge at

their own expense. Their location is favorable, and they are thorough and persistent in what they do. That is the foundation of their success. One or more good text-books should be studied, and bee-papers taken. This is within the reach of almost every one.

In beginning beekeeping few know at what season to begin. One time of the year appears to be as good as another. Time and again I have had people write to me wanting to buy bees at the close of the honey-flow when any profits for the next ten months were entirely out of the question; and in all my years of beekeeping I have never sold them a colony after the honey-flow was over, because I feel they were unconsciously acting unwisely.

Many others want to start on the cheap scale. Of course, if a success is not to be made of the undertaking, the cheaper one starts the better; but a bad outfit with which to start a business is a severe handicap. Box hives are bought, and these in the hands of a novice are often greatly injured when

FIG. 1.—Weighing a colony Don't guess at it.

transferring. I have known queenless colonies to be sold to a beginner, and afterward these have died without any cause apparent to the possessor. Then improper hives are often used with improper bee-spacing. However, the first step toward having bees is either to steal them, have them come to

you in the shape of a swarm, have some one make you a present of them, or buy them. In this article I purpose telling how to select them during daylight.

I remember when I first bought bees that I thought the weight of great value. Was not honey worth so much a pound? Did not the weight indicate honey? Why, yes (I have a feeling that way still, and honey is honey; and with me it is a rare thing for the apiary on an average to have too much honey). The novice then goes through the apiary, lifting the hives and selecting the heaviest. This is illustrated in Fig. 1 by weighing the colony. A nicely painted hive will also attract the beginner. But these points take second place.

HOW TO SELECT.

In purchasing bees, other things being about equal, I should want to buy them in the Langstroth hive. There are other hives as good as this for honey production. In fact, I would gladly have the frame an inch deeper, or even a little more, or a little shorter and deeper; but when I come to consider the handicap in getting supplies, especially when there is a rush, and the supply-dealer is fully occupied with getting out a regular line of goods, then I see the wisdom of using regular lines. Then if I or those after me want to sell the bees and fixtures, and I look back upon an experience of thirty years in beekeeping, then I know that the bees in the Langstroth hives, unless in a very restricted area, sell the best and bring the best prices. I know of many instances where beginners have acted contrary to advice, and in years to come they or their widows and families have found out the correctness of this statement. I would take the largest Langstroth hive I could get; but take a Langstroth, even if the hive is only an eight-frame. The frames, at least, are correct, and can be put into a larger hive.

But I would sooner buy a colony in another hive, if it were numerically strong in bees and brood, than buy a weak one in the Langstroth. If I were in the apiary on a fine day when the bees are flying, gathering honey and pollen in fruit-bloom (and that is the season to buy) I would select for my inspection the colonies into which the most bees flew in a minute. This is illustrated in Fig. 2. Move to one side so as not to im-

pede the bees. This will give proportionate strength of the bees. Select the best.

Next take the smoker, or have the bee-keeper take it, and examine the contents of the hive. If the combs cannot be taken out because they are not straight, then they are little if any better than a box hive. In fact, for transferring they may be worse.

If the combs are movable, examine for brood—capped, uncapped, and eggs—and

FIG. 2. —The beginner counting the number of bees entering in a minute.

the more of this the better, for it will soon be flying bees. If the colony is strong there will doubtless be drone brood as well as worker brood. There will be found two sizes of cells—one a little larger than the other. The brood in the larger will be capped rounding in contrast to the smaller capped flat. That in the larger cells is drone brood, and is undesirable. The drone comb is objectionable because it enables the queen to deposit drone eggs in the cells, and the bees to rear drone brood. The drones, for their production, use the energy of the bees. They use up stores in their production, but they never gather stores. A little poorer colony with worker comb is better.

Up to this point I have said nothing about the variety of bees. Give Italians the preference. They are a great deal better than the common black bee. Owing to the prevalence of European foul brood they are probably better than Carniolan bees; and they are better than Carniolan for the inexperienced, because it takes more careful management to keep them from swarming. A colony of black bees, if otherwise much superior, I should prefer, because it can be

changed into an Italian in six to eight weeks by introducing an Italian queen.

It is only after the above points have been considered that I would compare honey in the hives. A hive should not have less than 5 pounds of honey in it at any time—better even more; but a colony may have so much honey in the hive that the queen will not be able to find empty cells for depositing eggs. It is an easy matter to

feed a colony sugar syrup if short of stores; but if the colony is weak, the mere fact of its having stores in the hive does not enable the bees to feed and keep warm a large quantity of brood.

If the beginner can buy bees from a reliable person, he should put the onus upon him. Probably he will not sell his best colonies, but he will deal frankly.

Brantford, Can.

A GLANCE AT A FEW POINTS IN MY EXPERIENCE FROM A ONE TO 3000 COLONY BEE BUSINESS

BY J. J. WILDER

I was a successful beekeeper before I ever saw or knew the advantages of modern hives as they are now put out. I was using a crude movable-frame hive of my own get-up, and several sizes of them. At this time I had about 100 colonies, the most of which were in my own make of hives, and in one yard where my home or mother yard is now located. I am going to skip over this part of my beekeeping life, which started from only one colony in a box hive, which was a present to me.

It was about fifteen years ago when I saw my first modern hive, and could look into its merits. I saw that it was the thing to have, and obtained a catalog at once, also some bee literature, and spent my idle moments that winter in posting myself. During the time I hauled into the home yard about fifty colonies in box hives. I had been making good crops of honey all along, and it brought a good price. All returns were placed in the bank, to be expended to the best advantage in my bee business. So I bought some modern hives and put them up during that winter; and when spring came on, and the bees started to gathering nectar, I tried my hand at transferring, and I made a good job of it. Here is where I call the beginning of my beekeeping life. At this time I was making only a moderate salary; but the bees were given all my spare time, which was not much; but they never suffered from neglect.

INCREASE.

Increase was the next object. The colonies increased naturally somewhat; but this was not practiced long before I resorted to my own way of increasing—that of dividing up very strong colonies, especially those preparing to swarm, into two equal parts, making sure the queen went with the half to the new stand if possible, and that the other half had one or more queen-cells under develop-

ment. This way of making increase is kept up until this day, and all along I have found it the very best, all things taken under consideration. If more increase is needed it is made in the same manner in the fall or late summer; but nothing but very strong heavy colonies are used for this purpose. Never in my life did I sacrifice a crop of honey for the sole purpose of making increase. When the very strongest colonies (or those likely to swarm) divided up, did not make sufficient increase, both in the spring and fall, I purchased bees in box hives or any other kind, for the extra increase. My mind has never been changed about this, for I believe it is the most economical and satisfactory way a beekeeper can lead out.

CONTROLLING INCREASE.

In spite of progress I came fully to the point, as well as all beekeepers do, where the emergency brakes have to be applied. However, I did not come to it suddenly, for the let-up was a little slow. The bees came more and more under my subjection as I advanced, for I knew that I would reach this point sooner or later. My first step was to ventilate well at the bottom, or about one inch at each end of the hive, which secured me better results in quality and quantity of honey. Then more supers or storing room came into play than we might ordinarily expect. Also in making the weekly rounds to the apiaries during the honey-flow queen-cells were removed where increase was not wanted; and so, under such treatment, the bees have gradually grown out of their natural desire to swarm.

THE STOCK.

The point of stock is a great factor, and must receive some consideration. Under the best and most severe methods in certain localities or some seasons, certain races of bees will swarm too much, and such stock should not be adopted nor stock bearing the

FIG. 1.—J. J. Wilder's first yard in the process of being transferred.

reputation of being great swarmers. It is not worth while to obtain such stock and expect to breed or run this natural inclination out of it, for it will give you trouble sooner or later. To save experimenting and a lot of dissatisfaction let me say that you will not find such good traits in any bees that breed up slowly and then when the queens do become very active, and the colony reaches a very high pitch, soon fall back and proceed throughout the season in this up-and-down manner. Trouble is practically sure to follow at or near these high points, while no honey is secured at the low points.

What we want is a strain that will breed up early in the spring, and hold their own throughout the season. Such bees are good honey-gatherers, and almost non-swarmers. I have found the gray Caucasians far superior in these points to any of the other races of bees.

OUT-APIARIES.

Here was the critical point in my beekeeping life, and one that required more careful study than any other in order to proceed properly. Had it not been that the business was so well on my mind and heart I might

have done so if I had proceeded with nothing definite as to the extent of it. Friends were advising me not to start out on such a venture. Then, too, I had been out over the country and made investigation as to honey-plants in different sections. Also, I had visited some progressive beekeepers. These things, together with what I had read from bee publications, were sources of encouragement to lead me out and on.

Well, I started out with willing hands. Each year for a long time I increased my

bees and outyards nearly 100 per cent. I established the outyards from $2\frac{1}{2}$ to $3\frac{1}{2}$ miles apart, and extended the line of yards in six different directions as convenient to highways and railroads as possible. Some of the remote yards at the end of these lines were 30 miles from the home yard. During this time I had erected and equipped a good honey-house at the home yard, and had found that it was more economical to haul all honey to this house to be packed. This business was run for chunk honey solely, as the grade of honey would suit such packing better.

Our business was incomplete, and we went to the new field, about 200 miles away, where the honey-flow was suitable, solely for

FIG. 2. The first yard just after transferring.

FIG. 3.—J. J. Wilder's 23d yard, the home yard in the new field.

the production of comb honey in one-pound sections; and after establishing the home yard and packing-house at a good shipping-point we began circling outyards around it at a distance of three miles apart, hauling all the honey to the one packing-house to be prepared for market. As soon as the territory got too remote we went some twenty miles away and did the same thing; and when this branch was similarly established we went twenty miles further and established a similar branch. These three branches are operated solely for comb honey, and the honey-flow is about the same at each yard.

The business was yet not complete, and we went 100 miles from the home or mother yard and established another packing-house,

and around this established another series of apiaries, all run solely for extracted honey, which the sources of honey mostly justified. When this branch was established we went from it thirty miles and established another branch with outyards arranged in the same manner, and all run for extracted. Now our bee business is complete and the 3000-colony point reached, which is the extent of the business at present, and what I set out to accomplish.

THE LABOR.

The season I established my first outyard I hired some experienced help to do the necessary apiary work I could not do alone at odd times. This cost me as much as or more than I was making; but I had a job I could not lay down and pick up again, and

I had to hold to it, for a while at least. The following season I hired some more experienced help for the swarming season; and at the close of this season I had five apiaries established consisting of over 300 colonies. The next season I gave up my job, and went to the bees to give them my entire attention. I needed some raw help through the rush of the season, and for that purpose I picked

FIG. 4.—J. J. Wilder's 53d yard, the last one.

out a promising boy about 17 years old whom I thought I could make an apiarist. During his services with me I schooled him in bee culture, and the next season I put him on as a regular helper. But I needed more raw help, and so I advertised for it in a farm paper. I had my pick of a lot of applications as a result, and took the farmer boys who had never known any thing about city life, jobs, or public work, but had always been right on the farm with their parents. Out of the best of these, from time to time I have made apiarists and good reliable helpers in the business. I have found such help by far the best and most reliable. Later I tried considerable experienced help which never resulted satisfactorily. So I abandoned it entirely, and settled down to hire raw help and give it my own training. The best way I have found to handle reliable experienced helpers is to let them operate bees on shares, allowing them one-half for the other, except increase, which I hold. This allows them a chance to make more than they could in working for wages only. Where such an apiarist is competent a number of apiaries are turned over to him to operate, and he hires such help as he needs; but over all these must be a general overseer whose duty it is to see that the bees nowhere lack attention.

RETURNS.

I have never put one cent in bees that they did not make under my care. The fact is, I never had it, and I was \$227 in debt when I started beekeeping. This debt I had contracted three years previous, while in school, and nothing fell to my lot in the way of this world's goods; but I did plan for the bees to pay their own way and helped them do it. From the very first colony the bees paid their own accounts; but there was not much expense about the first 100 colonies, as their supplies were crude, and only lumber from the trash-piles of lumber-yards was used in making the hives.

I managed to live, and not draw any money out of the bees' treasury for outside purposes—that is, for any thing except for the bees, until I had over 300 colonies. Of course this gave them a good start, and ever since then I have drawn on the bees for all expenses; and, later, from time to time I have drawn on them for capital to make outside investments to the amount of over \$10,000, and my net income from my entire bee business is over \$4000 annually. All accounts against the business are settled when the returns are in at the end of each season.

Cordele, Ga.

WHAT FIVE DECADES HAVE TAUGHT ME

BY J. E. CRANE

As I look back over the years, it seems a long time since I first began beekeeping, for it is now just forty-nine years ago this month since I bought my first colony. It was a small colony of Italian bees, about half full of combs, for which I agreed to pay \$25.00. A little later my brother bought another, and we went into company in the bee business. By the last of March we had bought two more colonies of black bees in box hives.

These I thought I could readily transfer into movable-frame hives which we had made for this purpose. I had read all about how to do it by driving the bees out first, and embraced the earliest opportunity to do so while the weather was yet cold. Alas! the bees did not drive worth a cent; and I found after drumming for an hour or more that they refused to go up into the hive or box on top of the hive as I was told they would. In fact, the writers I had consulted had failed to state that driving bees out of their hive should be done in summer instead of during cold weather. How often writers

fail to mention some little matter that is essential to success, and then wonder that others do not succeed as well as they do!

Later we succeeded in transferring, and on the 4th of July looked up the queens of those black colonies, and soon introduced Italian queens in their places; but the season went by without a single new swarm or a pound of surplus honey. We increased our stock, however, by buying other colonies, and by the next spring we had ten or twelve hives of bees—not very strong but healthy. The season was good, and we made some increase and secured about 100 lbs. of surplus honey to the colony.

During the previous winter I had made glass boxes enough when filled to weigh 500 pounds. My father told me I had made up enough boxes to last ten years; but when he found we did not have half enough for the first season he changed his mind and thought he would like some Italian bees, and offered \$75 for the colony I first bought and its increase, and \$50 more for the honey they had made. I did not

care to sell, but bought a number of Italian colonies of Moses Quinby for him, and took him in as a partner.

We began sowing alike that year, which I believe was the first sown in Vermont. The season of 1868 was not as great a success as the previous year; but we made some increase and secured some surplus. In the fall I bought twenty colonies for myself; and as our company had some fifty we began the next season with seventy colonies. The season was propitious, and we secured some 3000 lbs. of most beautiful honey, nearly all in glass boxes that I had made ready the previous winter. I piled this honey in the cellar in a very artistic way, as I thought, and used to feast my eyes on it and show it with pride to my neighbors. Notices of this great crop of honey were published in various papers. In addition to the crop of comb honey I had made a honey-extractor and secured with it 240 lbs. of extracted honey from one hive—an unheard-of yield at that time.

The next spring I was married, and moved to a small farm several miles from my early home, taking my share of the bees (some fifty colonies) with me. During the spring my father was taken sick, and he turned over his share of bees (about twenty colonies) to me, so I started the season with seventy colonies; but it was hot and dry. There was no white clover that year; but the drouth shortened the corollas of the red clover so bees worked on it as freely as they usually do on white clover, and I got a small crop of honey with a few swarms. The next season was better, and I secured more surplus honey as well as increase.

I did not attempt in those years to increase very fast, thinking it better to get a moderate increase with a fair crop of honey than to make a large increase and little honey. I have since noticed that those who become excited when they get one good crop, or hear of some one who has, and make a rapid increase, are almost sure to go out of the business later. There are too many lean, ill-favored kine to eat up the well-favored kine to make it pay.

The year 1872 was propitious, and I secured some 4000 lbs. of comb honey in glass, which sold in the New York markets for *forty cents a pound*. I also increased my stock of bees.

After a time I had more bees than I thought should be kept in one place, and I started my first outyard with a good many new experiences. Later a cousin came to me and wanted to sell me his yard of bees; and as I wanted to occupy the territory where they were located I bought him out;

and so one and another, for various causes, came to me, wanting to sell their bees. I see now that most of my outyards were started in this way by buying small or large yards. This method of increase has its advantages as well as its disadvantages. The yard to be bought often has a different style of frame from the one the purchaser has; or if it is the same style, the frames may be one-fourth inch longer or a little deeper, so as to bother if they get mixed with the purchaser's. They may contain an unnecessary amount of drone comb. In one yard we bought, almost the first thing I did was to prune out the worse than useless drone comb. After leaving all that was necessary I melted up what I had cut out, and made some 70 lbs. of beeswax from it.

The advantages of buying a yard of bees is that you can usually buy much cheaper than you can make new hives and frames and fill them with foundation and bees. I find I have usually secured enough surplus honey the first season to pay for the bees, besides more or less increase. Many want to sell after a poor year; and as the next is likely to be a good one, if you buy you are in the swim. In one case I bought a small yard and secured enough honey from it to pay for it twice over, besides doubling the original number of colonies the first season.

As I have always lived where the cellar of the house was in clay, and rather damp, I have wintered mostly on summer stands in rather large and clumsy double-walled hives. Still I have sometimes had success in wintering indoors, and have nearly 100 colonies in my cellar at the present time. Cellar wintering is much more economical in food than outdoors. Both methods have their advantages as well as drawbacks.

I have always used an open-end frame, and now use almost exclusively the Langstroth standard size. I do not like the Hoffman closed-end frames, perhaps in part because I have never been accustomed to them. I should judge there are two or three times as many of them in use, or two or three times as many beekeepers using them at the present time, as of the open-end frame, judging from my experience in inspection work.

If the follower-board were made more substantially so it could be removed before trying to remove the combs they would work very well; but I most often find the follower-board of $\frac{3}{8}$ -inch stuff, where I find them at all, and so glued in with propolis that they usually tear apart before they come out.

If these hives were kept free of propolis

they would work better; but the average beekeeper does not keep bees that way.

If I have any advice to offer a beginner it would be: Get a standard hive that suits

you, and then stick to it. It may not be the best, but it will doubtless be better than to keep changing.

Middlebury, Vt.

BRINGING BEES HOME IN A SHIRT

BY WM. ROSEMERGEY

One day last month a friend and I went out to find a bee-tree. We got up on the mountain about two miles and walked right up to a swarm on a little sapling. I tried to cut it off near the ground; but when nearly cut through it went over and the bees all fell to the ground. They seemed quite cross, so I scattered a little thin honey on them and retired for a little while. About fifty yards away we found a big hemlock cut down, and saw that some one had taken the honey. So we came to the conclusion that our swarm had come from there.

We went back to look at the bees. They were in the air, but soon settled on the bark of a tree about six feet from the ground. My friend wanted that swarm of bees, but we did not know how to get them off, and had nothing to put them in unless we could get them into a shirt (I carried one swarm four miles in a shirt three years ago).

Well, to begin operations I took my bee-hunting feeder, scooped a few bees off the tree, and found the queen. Then I clipped her wing and set her and a few bees in the feeder on a limb where I wished them to settle; but the bees flew back to the tree, and the queen fell to the ground. I picked her up and replaced her and a few bees on the limb. This time she got out and I did not see her. I soon saw that she was gone, however; and, without moving my feet, I stooped down and began looking for her among the leaves. The bees also joined in the search and closed in around me. My friend said he thought they would swarm on

my head; so, not wanting that experience, I stood up, and, to my surprise, the bees were clustering on my legs and body. Crawling upward they got around my neck. I imagined I looked like a picture I saw in *GLEANINGS* some time ago.

My companion began looking for the queen on my clothing. My coat was off, and my vest open. He finally saw her go into the inside pocket of my vest, so I thought the best thing to do was to try to get the vest off, which I succeeded in doing by being very careful not to hurt the bees. Then I hung the vest on the end of a limb and stepped back a few paces, when the bees soon left me and went to the vest. In a little while all was quiet. My friend took off his open-front shirt. We tied a knot in each sleeve, and, holding two corners each, got under the vest, brought the four corners together at the top, and that swarm was fed and clothed without giving us a sting.

On June 4 I opened a four-frame nucleus to cut out some cells, but had made a mistake of one day, as a queen had hatched and three cells were torn open. The queen was removed from one; the next was dead in her cell, and the newly hatched queen was in the act of stinging the third when I got my eyes on her. She was in just about the same position as a queen depositing an egg in a cell. I rescued the queen in the cell, put a little wax on the hole, and caged the cell with three others, and they all hatched in a day or two.

Mayfield, Pa.

A NUMBER OF PRACTICAL WAYS OF USING THE BEE-ESCAPE BOARD

BY J. C. PARKS

As a super-cover I find the bee-escape board with a $\frac{3}{8}$ -inch rim as regularly made by bee-supply manufacturers to be more satisfactory than the regular super-cover or a wire-screen super-cover. The former is too fragile and too easily warped out of shape, and the latter is always so glued to the frames with propolis that in prying it off one soon bends the screen and destroys the bee-space.

If the beekeeper wants a sealed cover he can just lay a small piece of tin or thin

wood over the hole; or if he is a crank about upward ventilation he can cover the hole with a piece of thin foundation, press a piece of wire cloth down on that, then cover with burlap and put on the telescope cover. The bees will gnaw through the foundation and make as large an opening as they desire. As colder weather comes on they will begin to close it up gradually, but will never close it entirely unless there is a very large entrance, or it has some small opening somewhere else.

For feeding, the escape-board is very convenient. Just take a 5-lb. friction-top pail and punch about three small holes in its cover near one edge. Make a mark on one side of the pail, so that, when you put on the cover, you can let the holes you have punched come on the same side as the mark. Then when you invert the pail you can always tell when these holes are over the hole in the board.

The reason for punching the holes near one edge is that, if you wish to put two pails on at once, the bees can get at both of them.

When feeding, put on an empty hive body or super, and the hive-cover over that; and if the weather is cool, packing should be put around the pails.

If the hole in the escape-board comes directly over the cluster, thick syrup can be fed in as cold weather as we ever have in Alabama. If you wish to feed, slowly stop up with wax one or more of the holes in the pail cover.

To feed hard candy, just lay it over the escape hole, or partly so; put on your packing, and the bees will cluster right on the candy.

To introduce by the queen-cage method, turn the board rim side down; put the cage in the hole, wire cloth down. Close the hive, and do not open it for a week; and, nine times out of ten, your queen will be laying.

When working among my colonies I keep two or three extra boards with me. When I take off a super or hive-body I set it on a board with the rim side up and another on

top, so no bee can get out nor robber get in.

In carrying combs of honey or brood about the yard I use an empty hive-body with boards on the bottom and top. As an escape-board it has one fault. It cuts off ventilation, almost causing the bees above to smother in hot weather; and after they have all gone below, the honey gets too cool to extract well. This fault can be remedied in a great measure by boring several two-inch auger-holes distributed about over the board, and tacking wire cloth over them. When the board is in use for other purposes than an escape-board these two-inch holes should be plugged up from the under side to keep the bees from plastering them over with propolis. If they do get clogged with propolis they can be cleaned by pouring boiling water through them.

I think you can always buy these boards cheaper than you can make them yourself unless you are entirely out of a job, and they will be much neater than those you make. However, if you do want to make them, get some plain $\frac{3}{8}$ -inch ceiling—any width will do, but better 6-inch for ten-frame size, and some $\frac{3}{8}$ x $\frac{7}{8}$ -inch strips. The strips may be ripped out of the ceiling. Cut the ceiling in a miter-box, the outside length of the hive. Make a rim out of the $\frac{3}{8}$ stuff the size of the hive, and nail your ceiling on this rim, letting the tongue project on one side and the groove on the other, so they can both be ripped off. Make them in a form so they will be square.

Scottsboro, Ala.

THE EXPERIENCE OF A LIFETIME TESTING NEW SCHEMES

BY G. C. GREINER

If it were possible that one issue of GLEANINGS could be more interesting and valuable than another, the Nov. 15th number takes the lead. Several subjects are spoken of that deserve special notice.

Under the heading "A Word to Would-be Inventors," in that issue, the editor gives some valuable hints to beginners and those contemplating beekeeping which, if they will heed them, will certainly keep them on the right track. The whole paragraph under that heading so completely covers my experience of nearly a lifetime of beekeeping that I can heartily endorse every word of it. I am not a scientist; but being naturally inclined to take a great interest in all mechanical devices I have, during the last fifteen or twenty years, either actually tried or thoroughly investigated all the inventions that were brought out in the various

bee-magazines during this period—especially those whose originators claimed to be perfect swarm-controllers.

To judge from appearance, together with my actual experience, I invariably found all these new inventions altogether too complicated, too difficult to manufacture, and, consequently, too expensive for the everyday beekeeper who tries to make the two ends meet. To manipulate some of those complications according to the directions of their inventors would require a well-trained engineer or machinist.

The less experienced beekeeper or beginner who has not yet decided what kind of hive to adopt for future use can unhesitatingly take it for granted that the simplest, the plainest, and the cheapest hive is the most profitable for the beekeeper whose object it is to produce honey at a fair living

rate. Even a portico is a useless attachment, and in many instances cumbersome.

At the National beekeepers' convention in Buffalo, many years ago, Mr. Doolittle said in his address when discussing the various hives, "Is it the hive? No, it is the man." A more striking truth was never uttered.

Nearly forty years ago we started the manufacture of a double hive, claimed by some so-called inventors to be the only practical hive with which to make a fortune keeping bees. The brood-chamber consisted of two hive bodies—one inside of the other, with a $\frac{3}{8}$ -inch air-space between the two. It also had ventilators through both bodies to connect the brood-chamber with the outside world, and a portico for good looks. All in all, it was a tasty-looking hive when finished with two coats of paint. Great as were our expectations of this hive it did not winter well nor insure any special advantages over plainer-made hives in spite of its great expense. We soon learned that a cheaper hive would give us better results all round if properly managed. Mr. Doolittle's Buffalo truth dawned upon us, even at that early date.

On page 899, same issue, Mr. Ritland gives a description of his motor cycle transformed into a power saw for hive-making, which interested me very much. As a make-shift arrangement of this kind may give tolerably good service. I have studied the problem of using the power of an automobile in a similar way, but always came to the conclusion that a two or three horsepower gasoline-engine could be arranged to give better satisfaction. The cycle as well as the auto is a more or less cumbersome affair in a hive-making establishment. It requires room for lumber, room for the finished stock, and some elbow room to make our work convenient. But the main trouble with the average beekeeper would be the lumber question. Unless we are very favorably located it is almost impossible to secure lumber of desirable quality, such as our bee-supply establishments furnish us with our orders.

During last season's campaign I had occasion to order a number of hive-bodies and super outsides to make up a shortage. The work was all finished, except painting, when the foreman of a neighboring planing-mill called at my shop. I took special pains to call his attention to the quality of lumber used in my order; and I could see by his looks, although he did not say very much, that he greatly admired it.

But there is another point that would-be hive-makers should take into consideration. Many things we beekeepers need in the line

of our outfit require high speed and special machinery to manufacture. It would hardly pay to spend our time trying to make our own supplies when we have not the facilities to do it properly. We had better occupy our time in some other direction, and order our needed supplies from the regular supply-manufacturers. In this way we get things better and cheaper in the end. In case we should desire goods of special construction, not listed in the catalogs, an order with correct description and measurements will bring them to our doors.

Another interesting feature of the Nov. 15th number is the views on the winter-case problem by Mr. Ames, pages 889—892, and Mr. Holtermann on the three following pages. I do not wish to cross bats with either of the two gentlemen; but the experience of many years of beekeeping compels me to differ with them on several points. Having made the production of extracted honey my main business for years, I know from almost daily observations that for convenience of management a combined winter and summer case, or even bottom, as described and illustrated by Mr. Ames, is out of the question. We could overcome its inconveniences better when producing comb honey than we could when producing the other; but for convenient, unobstructed, and systematic work in the beeyard, hives must be placed on separate stands in straight rows, about two feet between the hives, and from six to ten feet, according to the space at our command, between the rows.

The objection of some beekeepers, that the uniform appearance of a beeyard frequently causes loss of queens, is more imaginary than real. It may confuse the human eye, but not the animal instinct. A queen is no more liable to miss her home than a dog to lose the trail of his master. Nature's instinct will guide them where human skill and ingenuity will fail.

The confusion Mr. Ames speaks of is a new disclosure to me. It is something I have never experienced. If the cases are properly made, if bees are in winter position, if tools and everything to work with are on hand, packing in the fall and unpacking in the spring goes like clockwork. Not a mishitch of any kind, nor confusion, need be encountered.

Judging from the illustration, Mr. Ames' cases may be a little more artistic in appearance than mine—a point I admire; but for efficient service they are no better. Mine, made of dressed matched lumber, covered with rubber roofing, are as nearly air and water tight as mechanical workmanship can

make them. The metal binding strips Mr. Ames uses are all right, neat, and tasty. I use wooden half-round strips the whole length of the roofs, which also fill the bill.

May I ask Mr. Holtermann what becomes of the excess of moisture in hermetically sealed hives, for which he feels so anxious to furnish an exit through porous packing above the bees? I never have any trouble from moldy combs, neither do my bees suffer, so far as I know, from this moisture. It seems to be natural instinct of bees to seal their winter quarters as nearly airtight as bee-glue can make them. If this were detrimental to the welfare of bees nature would dictate otherwise. To be sure, we do not always follow nature's law in every respect, nor the animal instinct indiscriminately; but the nearer we comply with either, the less liable we are to make mistakes. If it serves our purpose any better, if we can gain any advantages by partly or entirely ignoring nature's rules, it would be shortsightedness not to do so.

Since I have wintered my bees for many years with sealed covers, it proves that upward ventilation is not necessary or desirable. With about six inches of chaff packing above the cover, the much-dreaded

formation of frost or ice under it is next to impossible. Can it not be possible that bees need this moisture for their existence during winter? On the other hand, if Mr. Holtermann has always wintered his bees with upward ventilation through porous packing, and has thereby secured some benefits, it simply proves that neither method can pass as a cast-iron rule. Bees will winter, ventilation or no ventilation, and they may succumb with either. There must be other factors that decide the matter.

A word about the lumber. I cannot agree with Mr. Holtermann that half-inch lumber is better than one-inch. A winter case built of half-inch stuff is not nearly as strong as when the thicker material is used. Thin lumber does not hold nails or screws as well as that twice its thickness. We have to pay the same for one-half as for one-inch lumber, so there is no gain financially by using the thinner kind. To let the sun's heat penetrate more readily is of very little account. The object of a winter protection is not so much for the atmospheric heat to be absorbed as for the inside animal heat to be retained. Which of the two kinds will do this more effectively?

La Salle, N. Y.

A BRIEF HISTORY OF MY BEEKEEPING LIFE

BY G. M. DOOLITTLE

When I was about ten years old father bought a colony of bees, much to my delight. This colony increased till at the end of four years we had some fifteen or twenty colonies, all in box hives made of rough lumber as it came from the sawmill, each having a capacity of about 2250 cubic inches, being generally a foot square and 16 to 18 inches high. When I was 14 a second swarm began to issue as father was about to leave home, and I was told if I would save it I could have it as my own. As is the custom with most after-swarms it alighted near the top of a tall apple-tree; but, not to be beaten, I climbed to the "dizzy height" and secured it in a cracker-box, as all the hives we had made were occupied by earlier prime swarms. I watched this colony work with far more interest than I did any of the other colonies in the apiary. The box and contents were left under the tree the swarm alighted on, which was distant from the house and the apiary some twelve or fifteen rods. As fall drew on I often "hefted" the box on cool mornings, finding that a gain in weight, quite perceptible, was made as the buckwheat bloom progressed, till, after a little, I had quite reasonable hopes that

they would have sufficient stores for winter. A little later, as frosty nights came on, I would go mornings and slightly rap on the box to hear the bees give me a "good morning" salute by their answering buzz. One Monday morning I gave the usual salutation; but, instead of the salute, I got a hollow vacant sound; and on lifting the box I found it empty, with the inside near the bottom smoked and charred in the killing of my pets, which I later found was done in a piece of woods a third of a mile away.

That ended my first experience as a bee-keeper, as in "taking up" an old colony or two a little later on father found that the much-dreaded disease now called American foul brood had gotten a foothold in our yard; and it progressed so rapidly that the fall of the next year found us without a living colony, father taking the precaution to "brimstone" all that were living before robber bees had a chance to carry off the diseased honey. This honey, such as did not have brood mixed with it, was strained, scalded, and used, and the rest of the combs were rendered into wax.

I was still so much interested in bees,

however, that, whenever I ran across any thing in the *Rural New-Yorker* (the only paper father took in those days), about them I read it with more interest than I did the "story page."

The season of 1868 was an extra season for bees—so much so that colonies filled their hives, clustered out, and built combs under the benches the hives stood on, some colonies storing from five to twenty pounds there. This made bee-talk very common in this locality, and caused my old love for the bees to burn brightly again, so that the spring of 1869 found me with two colonies of my own as the starting-point of my real beekeeping.

Wishing to know all the minutiae of this interesting pursuit I procured all of the bee-books of that day, and subscribed for the bee-papers. And to these books and papers I have always credited very much of the success, whatever it may have been, that has come to me in all of the years since the season of 1868.

As my ambition led me toward the practical side of beekeeping, "Quinby's Mysteries of Beekeeping Explained" captivated me beyond all of the others; and after all these years the turning to the index of that old book brings to mind pretty much all that the hands, now moldering in the dust, wrote nearly three-fourths of a century ago.

To tell the truth, beginning with 1870, beekeeping for the next thirty years was little less than "one round of endless pleasure." I dreamed of bees nights, and thought of them during my waking hours to an almost absorbing extent; and to-day I am still a student, believing that there are many unexplored regions (which I should like to explore would circumstances permit), and much room for still deeper thought, even on the practical part of this pursuit.

Besides the books and papers, Elisha Gallup, a writer on practical beekeeping during the seventies and early eighties, helped me very much through his private letters. I still have a stack of these some three or four inches high. His great patience with me and my questions has been the "mainspring" which has "moved me out" in answering the questions regarding beekeeping sent in to me. Many and many have been the nights during the past forty years in which I have been up long after I ought to have been in bed, answering questions as best I could in order that I might pay the debt I owe E. Gallup; for he would never take one cent further than postage for all the help he gave me. He, too, has passed to "his long home."

In 1870 I wrote my first article for pub-

lication, sending it to the *Apiculturist and Home Circle*, published in Mexico, Mo. This article was written over three times before I dared let it go, as I feared that it would never be published. But the editor saw fit to publish the matter, and since then I have been "scribbling away," honestly trying to help some one a little, in order that, in a small way, I might compensate for the great amount of knowledge I have gained from the writings of others.

The two colonies bought in 1869 had increased so that I started the spring of 1877 with 67 colonies; and from an old diary of that year I find the following:

I have a chance to rent the old farm which I have been working on shares for father the past 11 years, and so I start out this year with nothing but the 67 colonies of bees to depend upon, this first day of April, 1877. It looks a little venturesome, but I hope it will come out all right.

Under date of May 27 I find this:

Apple bloom, which has given a good yield of nectar, and given the bees a good supply to last till clover bloom, has also given quite a start in the boxes that are on the best colonies.

Again, date June 13:

Have decided to work two colonies for extracted, and 65 for box honey.

August 3:

White clover began to secrete nectar June 17, and on the 20th the most of the colonies were well at work in the section boxes. Basswood opened July 14, and lasted till the 28th, which, with teal since the 20th, yielded abundantly. Now the teal has failed, and I can work only early in the morning and after sunset, taking off honey on account of robbers.

August 31:

Buckwheat began to yield nectar the 16th of this month and closed the 28th, which is, without doubt, the last surplus for the year 1877.

October 1:

The result of this season with the bees sums up as follows as to honey:

Box honey (white), 8761; box honey (dark), 1523; extracted, 893. Total, 11,177. The average yield from the 65 worked for box honey was 158 pounds. Average yield from the two worked for extracted honey, 446 lbs. Average from the 67 colonies of both box and extracted honey, 166½ lbs. The best colony worked for extracted honey gave 566 lbs. Best yield per day was from July 21 to 24, being 66 lbs., or 22 lbs. per day. Three colonies worked for box honey gave 896 lbs.; the best, 309; second, 301; third, 286. Several others did nearly as well, but no record was kept.

November 29:

Honey all sold. Received for what I could spare, \$2492.28. Have now concluded that I can "run alone" with the bees, so have disposed of my interest in the old farm and start out as a specialist in apiculture. Since starting in 1869 the bees have paid me a little over \$6000 above all I have paid out for them.

After 1877 I increased the bees till I had about 250 colonies; but in 1880 father became helpless and I had to give so much of my time to him for the next four years, or till he died, that the number was reduced to

an average of about 100 colonies. Two years ago last July my wife, who had been of very great help to me during all these years, had a shock of paralysis, which left her helpless; and in order that I might be the main one in caring for her I now have only five colonies—just enough for a little relaxation from the many cares resting upon me.

In closing allow me to say that, while I had many more colonies from 1877 till 1900 than I had during the first-named year, yet in no one year after 1877 did the income from the bees equal the amount I secured in that year, although some years it very nearly reached it. Reason: Not till 1888 did I sell a single pound of white comb

honey for less than 25 cts. a pound, and in 1874 my whole crop of comb honey brought 28½ cts., the dark being included with the white. Several years during the 80's and early '90's, ten to eleven cents was the average, and in 1899 the average, when footing up for the whole crop of comb honey, was a little less than 9 cents a pound. Furthermore, since 1900 basswood has failed to give the crop it formerly did, through failing to secrete nectar some years, and because all that was available for lumber was cut off, owing to this lumber bringing \$30 to \$35 per 1000 feet. Better basswood lumber could be bought in the '70's at from \$8.00 to \$10.00.

Borodino, N. Y.

THE COST OF RUNNING AN AUTOMOBILE

BY A. W. SMITH

Your editorial statement, page 789, Oct. 15, that it costs ten cents a mile to run an automobile for outyard work, must refer to a \$2000 or \$3000 truck. Allow me to give an idea of what it costs me to run my little old knockabout Ford. Last March I bought an old touring-car. With saw and ax I chopped and sawed off the rear seat with its part of the body, and put on a home-made box, just the size to hold a certain number of hives.

Well, my speedometer shows I've run this machine a little over 3000 miles to date. Do you suppose it cost me \$300 or more to do it? I know it has not cost me a fourth of that amount. We do all our extracting at home, hence we have given the machine plenty of hard work. For instance, one day we drove it 90 miles, stripped hives, brushing bees from combs, and 45 of those miles the old auto carried such loads as we should not put on. Do not for a moment think it cost me \$9.00 to do this. Call it a fourth that amount, giving discount for cash, and you will be nearly right.

To do that with a horse would likely cause some depreciation. Formerly, when using horses it took from two to three hours to drive over, and an hour longer to drive back if heavily loaded, and the driver had about done a day's work if it was a hot summer day. Again, one does not care to drive a sweaty horse into a yard of 125 hives, but he can run an auto right up to their front doors. If my old Ford ever was stung I never heard her complain or prance about and kick over the traces as some horses do in a similar position.

Then see the fun one has in sailing through

the air at a 25-to-35-mile clip. Repeatedly I have made above twelve miles with the machine in 25 to 30 minutes, and on arrival was ready to get at my work. It is not every beekeeper's horse that can make 20 miles per hour, and keep it up night and day if necessary, even with the level roads we have here.

I would say for a beekeeper, buy a runabout; knock off the back hood or cover; put on a box to suit the taste, then put on steps or mud-guards, one or two long tool-boxes, and "go it." If the beekeeper does not know the steering-wheel from the differential, I would advise him to buy a new car and run that carefully until he does know something about an auto. If he has a friend (good and true) who understands autos, and wishes to buy a used car, he might get that friend to go with him and examine such a machine. Even then it is well to keep close enough to see the seller is not asked how much is in it for the expert.

Some might like to know the course I pursued. Through the winter months I would go through garages and sales places looking for used cars; but although there have been hundreds of thousands of machines built of the make I wanted, there seemed to be very few offered for sale, and not a single one could I find for less than \$300 and up to \$400. At the same time I could find a great many of the formerly high-cost cars at \$200 to \$250. The more I could not find the car at my price, the more I wanted one.

Finally I made up my mind it was a Ford or none. The big cars that carried 4-inch and 4½-inch tires were heavy, and it might

cost 10 or even 20 cents per mile to run them over country roads; and I had seen them stuck in mud or sand that I know my car would go through with a smile. I finally learned of a man some miles away who had several used machines for sale.

He was overjoyed to see me (look out for the glad hand when you talk with auto dealers). He showed me a couple of old cars I did not want, and then the one I bought. Said he, "In that car is the best engine I ever ran," which I think was the truth; but some other statements he made I know were lies.

"How much?" said I.

"Well, seeing you are a friend and came away over here, I will sell to you for \$275."

"Well," I replied, "seeing as how I am a friend of yours, I won't pay it. What time does the first train leave for home?"

In the course of the conversation he asked me what I thought the machine was worth. I took \$250 from my pocket, and, handing the cash to him, said, "If you will give me \$10 and the Ford it is a trade." His wife slipped the bills into her pocket, and I knew that I would never see them again, and probably *he* would not.

"Shall I go home on the train or by road?" I asked.

"It is a shame; but as trade is dull at this time of the year, and I want money, I guess I had better take you home."

I know to a gallon how much gasoline I have used, and how much of the best oil, and can form a fairly correct idea how much wear and tear on tires has taken place. Then you speak of depreciation. According to your scale it would not take long to arrive at a point where there would be none. I believe my old car has reached it; but I hope you will understand she is a long, long way from the scrap-heap. I would not sell her to-day for \$240. You say repairs will run from \$50 to \$100 per year. A beekeeper has no business inside a garage door unless he wants to be robbed. If he does not know how or cannot learn how to do his own repairs, he'd better buy a wheelbarrow.

Of course, one may be careless or drive recklessly, and have an expensive accident. I had one. I was driving to an outyard that I was getting in shape for winter, when I met a farmer with twenty cows. My machine hit one Holstein a glancing blow on the starboard hind quarter—result, one broken glass in wind-shield, \$3.50; one broken glass in headlight, 35 cts.; one bent mud-guard, ten minutes' work; one angry farmer, and one surprised cow. I had been driving quite slowly; but had I been going 35 miles per hour *it is* quite possible the cow would have been more surprised.

See the pleasure one can get from an auto. For instance, suppose Mathilde and I wish to take a little ride of 100 miles and call on beekeeping acquaintances. 'Thilde and I get in with full expectation of going there and coming back; but if we knew it would cost ten cents per mile, or \$10, would we go? No, sir; we'd put the \$10 at compound interest, sit in the hammock, and coo.

I never had much experience in driving those heavy big-tired cars; but I am willing to concede it may cost 10 cts. per mile to run them. I can not see how one can run up such an expense driving a light-running auto unless he goes joy riding.

Birmingham, Mich., Nov. 7.

[Our figures as explained in the editorial referred to were for the average automobile costing about \$1000, and we had reference especially to our own 1000-pound truck. We stated that the depreciation and tire expense on a Ford, at about \$500, would not run over half, or perhaps five cents a mile, including every thing. We are quite prepared to believe that the expense in running a second-hand Ford bought for \$240 would not be over half the latter figure, and so, apparently, we agree quite well after all.

We do not wish to be understood as proclaiming that every time the truck is run five miles it costs us 50 cents. We simply mean that, *on the average* for a car of this capacity, the expense, counting interest on the investment, depreciation, etc., is apt to be not far from 10 cts. a mile.—Ed.]

WHY I FAILED IN BEEKEEPING FOR A DOZEN YEARS

BY WALTER JACK

"I have no hard-luck story to tell, but I know that I might have succeeded much better had I studied the literature of the business," was the remark of a farmer who had an apiary. This farmer gave me a few interesting facts concerning why he fell

down in the business, and I will repeat them here.

"I see no reason why every farmer cannot keep a few colonies and produce the family honey supply; but when the farmer who thinks he can make easy money by engag-

ing in beekeeping he is going to lose a great deal easier. The farmer should read the books and the periodicals, and study the catalogs devoted to the art. This is where I failed. I thought I could keep bees any old way; and when I was in doubt I would wait until I saw some fellow who, I thought, knew a little better than I did. I fiddled around for two or three years, asking of this one and that one the simplest questions about beekeeping. I could have learned in two or three days' careful reading more than I learned by feeling about in the dark.

"I looked about for equipment. I bought old hives, the covers of which were rotted and worm-eaten, and the frames ready for kindling-wood. I guess I had a lot of swarms that were ashamed of the quarters I offered them and they 'flew the coop.' I lost bees year after year from disease and dissatisfaction. My colonies wintered poorly, and it is now a wonder to me that any survived. One year I dropped from about thirty stands down to about two or three. The bees seemed to swarm whenever they pleased, and at such times as I would be in a back field pitching hay. I knew of no method of controlling swarming; and when I did hear of them, they sounded as strange as the stories in the Arabian Nights.

"A beekeeper told me that I would have to get down to business, look after my bees, buy some good equipment, and read up on the art. I finally arranged to lease my apiary to him for a year, and my cash return was ten times as much for the one year as it had been for six years before that, and I was at no loss in time. The next year I thought from the few things I had observed that I could handle the bees myself. The money of the previous year looked good, and I thought that, with the increase, and with the tenant's share, I could have a nice sum in the fall. When I took hold of the bees I had a nice account of enthusiasm to draw on, but I fell into the old rut. I had a dairy of twenty or twenty-five cows. My attention was again divided between the apiary, the farm, and the cows, and the bees got the least amount of attention.

"My bee tenant told me that, were I to make money out of my bees, I should look after them, let the scrub cow hustle for herself, and I would make more out of my bees than out of my dairy. I believe him now. I believe I should have been cash ahead had I sold the scrub herd and just devoted my time to the bees.

"Last year my son returned to the farm and made a proposition that he would look after the farm, the dairy, and all crops, and turn the poultry and the bees over to me.

Well, I thought that I could help out on the farm, and again I neglected the bees for the dairy. I thought it was up to me to boss the farm; and the best end of the farm, the apiary, failed to return the anticipated amount, yet it paid, even in the face of neglect.

"I have been keeping bees for a dozen years. I see why the farmer fails to make the success he should. He divides the time on the farm with the cows, the hens, the horses, and the bees. He does not make the apiary a department of the farm. He should establish it on the same basis as the millinery or the rug department in a department store. These have to pay their way or they are eliminated. If the apiary is recognized as a department which will pay its way, and the farmer studies beekeeping, and keeps abreast of progress in the art, he can make it go.

"If scrub cows are taking time from a profit-producing apiary, cut out the scrub cow or turn her over to the hired man and look after the bees.

"Give attention to marketing the product. Here is another reason for my failure; and with neat cartons and cases for the honey the product will find its way to customers who ask for repeat orders, and bees will pay."

Ashtabula Co., O.

Bee-dreams of Golden California in Winter

BY GRACE ALLEN

I walked within our yard one winter day
When not a bee from out a hive had stirred,
When soft, across the air so chill and gray,
It seemed as though a droning song I heard.

"You think we sleep, and only sleep?
Across our darkness visions sweep
And through our silence whispers creep
Of golden California!
We thrill with dreams of cloudless skies,
Where sunlit dawns and days arise;
Our winter sleep is stirred with sighs

For golden California,
Where every stroke of passing time
Is like a vibrant, ringing rhyme,
And winter's days, like summer's, chime
In golden California.
Where roses redden through the hours,
And bees that pause for naught but showers
Hang o'er the manzanita flowers
In golden California."

THE POET'S REPLY

(with apologies to our readers, as it's sorta 'tween us and the bees).

Dear bees, we're in the same position!
And now we pray you softly listen—
This year they hold an exposition
In golden California;
So please *you* store a wealth of honey,
Then we will calmly take the money
And hie us to that land so sunny—
Golden California!

Heads of Grain from Different Fields

The Backlot Buzzer

Many a novice has heard that "birds of a feather always flock together," and then gone and tried to put two queens in the same hive.

Some Answers to Questions on Starting with Bees

Hereafter no one need expect me to answer letters privately, even though a two-cent stamp is enclosed, for I am too busy with other work, and cannot take the time to answer them all. Although beekeeping is my hobby, it is only my side line, as I am a rural mail-carrier, and am on the road six hours in winter, and the spare time I must make use of for preparing spring operations.

The following are answers to questions sent me.

I would start in the spring by buying a colony of bees. I would use only standard factory-made hives the size depending on location and whether running for comb or extracted honey. The ten-frame is best for central Wisconsin, especially for extracted honey. I use nothing but a two-inch bottom, open on two sides, which I get from Gus Dittmer.

Bees can be kept on almost any town lot as long as they are compelled to rise in their flight to and from the fields by some object as brush, bush, trees, fences, etc. If handled at the right time of day and night, days clear, and during a honey-flow, they will not bother. Most lots have some out-of-the-way corner. I advise starting in a small way, and with good gentle Italian bees.

As to profit, this year was poor, but I sold \$120 worth of extracted honey from 18 colonies, and kept a barrel for myself and friends.

The number of colonies that can be kept in one place depends upon the country. I had 24 last season, and increased to 33, which I am wintering in a cellar. Half a block from my place are six colonies; two blocks away there are 25; half a mile north are 50 to 55; $\frac{3}{4}$ mile southwest, 35 or 40; $1\frac{1}{2}$ miles south, 30, besides a lot of farmers who keep one and two colonies apiece. Last season I was the only one around Fall Creek who had any amount of honey to sell. **CARL BAUMBACH, JR.**

Fall Creek, Wis., Jan. 7.

Finds Smoke Introduction Successful

I note a tendency to throw cold water on Mr. Miller's "direct-smoke introduction of queens" in bee publications lately. I consider it one of the best helps in bee manipulation of recent date. After the basswood flow I went through the beeyards caging the best queens, introducing them to the ones with poorer queens; and, when fixing them for winter, I was surprised to find so many young queens in colonies from which the good queens had been removed, and so many of the older queens accepted satisfactorily.

In carefully looking over the reports, there is usually some cause of failure evident among them, as, for example, trying to run the queen in when the robbers had grown a little bothersome while trying to find the poor queen. Or perhaps some little detail of the plan was overlooked.

In a late number of the *American Bee Journal* Miss Wilson, of Marengo, Ill., says they let the hives remain queenless one day before smoking in the new queen.

The beekeeper should have the good queen caged and all ready to smoke in as soon as the poor queen is caught out of the hive. Of course he should remove the poor queen as carefully as possible to avoid disturbance. The real point is to get the new queen into the hive so there will not be a bee but still thinks she is their old queen. Keeping a colony queenless one to three days gives the bees a chance to raise another, and, consequently, makes it harder to introduce a new queen.

Colo, Iowa.

False Face instead of a Bee-veil

The first time I had any occasion to handle bees was when the old gray mare turned over one of the bee-gums, and we had to set it up again. I told my father to wait and I would get my false face. The mask was made of an old black hat with red bound around the eye holes—the whole combination just the thing to "sick" the bees after me.

I slipped up to the overthrown hive, and all at once they came at me like hot shot. They got under the false face in a moment, and then the fun began. As it was tied on with new strings it was hard to get off; but I finally tore it off just the same.

This quieted my bee fever for several years; but after a time we got some more, and since we all liked honey so well they were robbed to death. The following season I began reading, and going at the business in a different manner. I secured some good bee literature, and read up on the subject. I can now handle bees in a more businesslike manner; but I do not use my old false face. I handle them without veil or gloves. I have twenty-four colonies all in good condition.

Last fall I had a case of foul brood. Since I discovered it so late I could not save them. I just burned them—frames, combs, and all.

Hatcher, W. Va.

I. C. QUEENBURG.

Where the Power Truck Saves Time

I keep 600 colonies in six out-apiaries, and run for comb and extracted honey. Last season I bought a one-cylinder ten-horse-power motor truck, 1500 lbs. capacity. I find it strong enough, with sufficient speed for all purposes.

My apiary is arranged with a road through the center. I enter the apiary with the truck and supplies, stop near one end, attend to the rows near the truck, move up a few rows, and so on. When done with one apiary we load on every thing that goes, and are off to the next.

It takes the place of one double team and spring wagon; also one single horse and rig. It saves about one man in time, besides making the work much easier and more pleasant. It is especially valuable for moving bees and taking off comb honey after the flow has stopped in the fall. Two men can go to an apiary after the flow has stopped, take the lids off, smoke the bees down, take the supers off, and stand them on end behind the hives, then go over them, smoke the bees out, brush them off, load them on, and take them away without having any spoiled by the bees—something impossible to do with a team.

Standish, Cal.

H. H. HARTMAN.

Beemen, Wise and Otherwise

Out in California there is a beekeeper who has kept bees (as well as moths) for over thirty years in the same yard. Some of his hives have the bottoms nailed on tight, while in not a few of them I found the frames nailed fast in the hive. Among the conglomeration I counted eight different kinds and sizes of brood-frames and five sizes of hive bodies.

Several barrels of slumgum had been thrown on the ground and in boxes, I suppose to help the moths over a poor honey season. One pile which had been undisturbed for six years contained some sixty or seventy supers full of moth webs.

In Hot Springs, Ark., a beeman had on one hive three supers, one reading "Bottled in Bond," another "Heinze's Pickles," while the one on the top announced a dye for whiskers. The bees seemed to be quite happy notwithstanding.

Here's another beeman I know—J. Ross Miller, of Montrose, Col. A worker? One morning when I was his hired hand I woke up to find the lamps lit and breakfast on at about five o'clock, my usual time for getting up. My boss had beaten me ten miles. He had hitched the team, driven that distance to an outyard, and had brought back a load of supers so we could all keep busy scraping and grading.

Mr. Miller is certainly one of the best graders I ever saw, while as an inspector he beats them all. I helped him pile up and burn several hives of his own bees. One had three full supers of nice-looking honey. He simply burned bees, hives, frames, supers, and combs down to white ashes. But that stamped out the foul brood. He has five outyards, and takes his assistants out in an automobile.

One of the best-known beekeepers in this country once spoke of me as "the wandering beeman." Wandering is right. Beeman is wrong. But I claim to know more about bee locations than a wild goose.

Hot Springs, Ark.

Shipping Bees in a Refrigerator Car

The experiment of shipping bees in a refrigerator car was made by F. Grabbe, Libertyville, Lake Co., Illinois. One hundred colonies were put into a car that had been iced twelve hours before loading. The car left Libertyville about noon, August 15, and was run direct to Chicago, thence to Burlington, Iowa. There the car was reiced, and continued on its journey to St. Peters, Missouri, where it arrived August 19 at 4:00 A. M. The bees were in excellent condi-

tion, and were loaded on wagons and hauled four miles north, near the Mississippi River. The temperature was about 95 in the shade while the bees were in transit. He shipped the bees for the Spanish-needle honey crop in September, and got about sixty pounds of extracted honey per colony.

The freight charge on the car from Libertyville to St. Peters was \$70. The two ings cost \$6.50, and the hauling to the river cost \$10, or a total of \$86.50. The distance covered was about 500 miles.

Mr. Grabbe has had wide experience in conducting perambulating apiaries. He was connected with an enterprise in which a steamboat and several barges were used in transporting bees from place to place on the Mississippi, culling of willow and other bloom being the object. The expense, however, in maintaining day and night crews on the steamer ate up the profits. All moves were made at night, and on this account day and night watches had to be maintained.

Was the Leaf the Signal for the After-swarm?

I hived a very large swarm at 11 A. M. They went in nicely, and, to all appearances, were well satisfied. I was observing them at 4 P. M. when a bee alighted on the hive with a wad of leaf in its mouth. All at once the whole swarm was thrown into consternation, and they began to come out, and absconded. I am as positive of the matter as I could be of any thing of so minute proportions. Has any one else ever observed any thing similar? Is it possible that this was a signal for absconding?

Rising Star, Tex., Aug. 14.

J. W. BOASE.

[There are so many cases of swarms leaving the hive after a few hours that it seems to us more like a coincidence that the bee with the piece of leaf should have alighted at the precise moment when the swarm was preparing to abscond; that is, in our opinion, the bee with the leaf merely happened to alight at the same time, and this occurrence probably had nothing to do with the bees leaving.—ED.]

Make Your Own Rubber Bands

On page 952, December 1, E. J. Ladd suggests the use of rubber bands for transferring. I just called up a large rubber store, and find that rubber bands cost \$1.75 a pound, while a pound contains about 40 bands of the size necessary.

Get wide and make your own rubber bands. If you haven't an auto, buy old inner tubes at from 6 to 10 cts. per pound, which you can cut up into wide or narrow bands as you choose. Get tubes large or small, according to the size of the bands you need. These will make stronger bands than any thing you can buy new at a rubber store.

Flour Made from Sweet Potato as a Pollen Substitute

After experimenting with different kinds of imported meals and flour, I find the bees do not take to any kind readily. The next products I tried were flours which I made from the green banana, sweet potato, and cassava.

Each flour was put in separate trays and placed in the apiary, and a small piece of comb containing honey was put in each tray to attract the bees.

The flour made from the sweet potato gave the best results; and if I could have pulverized it as fine as wheat flour, the bees would have taken it more readily.

OUR HOMES

Editor

In the sweat of thy face shalt thou eat bread.—
GEN. 3:19.

THE GREAT ARMY OF THE UNEMPLOYED.

The Home paper below was dictated before coming to Florida last fall. Before using it, Ernest wrote me as below; but as it is already about the usual length I plan to take the matter of "the worthy unemployed" up in our next issue.

Dear Father:—When you wrote this, conditions were quite different from what they are now. Possibly you saw in the Cleveland papers that there were 61,000 men out of employment in Cleveland alone, a large majority of whom appear to be worthy men. I asked two or three prominent people in Cleveland if this could be possibly true. They said that it was absolutely a fact. In your write-up here you speak as though only the dissatisfied or incompetent were out of work. I thought possibly you would like to modify this before it is published.

A good friend at Palatka, Fla., has written me two very long letters in regard to this matter. I answered briefly by saying that here in my Medina home, and down in my Florida home as well, there is a constant and unfilled demand for competent laborers, especially good mechanics. Of course there are more or less tramps claiming they cannot get a job. One such came to me just a few days ago. He was fairly well dressed, a good strong fellow, and he wanted something to eat. I told him I could not give him any thing to eat, but I would give him work in the lumber-yard. He snapped me up quick by saying, "How much do you pay?" I told him we would pay him what he was worth. Again he asked, "How much do you pay?" I explained to him that I could not make any bargain in regard to the pay until I saw how capable he was, and how much he was worth. I told him the foreman of the lumber-yard would be fair, and pay him what he earned compared with the other help. He went on grumbling and cursing.

Now, this is a fair type of the unemployed that have come to my notice. There are a few who seem to be honest and willing, but who are too stupid to do things right. Well, in my answer to the brother I have mentioned, I told him he was crazy to insist that merchants should sell all their goods at cost, and that the manufacturer should pay his help all he earns, without any margin to pay for the use of capital and incidental expenses. In his reply he takes up a subject I had not in mind. He says Uncle Sam is selling goods and doing work for the people at large without any profit, and this is all right. I heartily commend it. I am glad to see Uncle Sam

take charge, not only of the mails, but also of the banking, at least to some extent; also taking charge of good roads; and I should rejoice to see him take charge of telegraphs, telephones, and even of railways when we as a people are ready for it. This man from Palatka is soured against the government; he is soured against God, and I fear he is soured against his fellow-men. His vision is obscured, as it seems to me, so that he does not see the good in this world of ours. He mentions a neighbor of his, a poor man with a family, who came to him with tears in his eyes, saying his folks were suffering, and yet he had traveled day after day hunting for a job. Well, now, although I do not know the circumstances I cannot help feeling sure that this man is either incompetent or else he will not do faithful and honest work when he gets it. He and the writer of the long letter have got into a fashion of thinking that Uncle Sam should relieve them from *responsibility*, hunt up work for them, and feed and clothe them, etc. Right here let me state that the philanthropic societies in our cities all over our land are fast finding out that there is no quicker way of spoiling a man, woman, or child than by doing things *for* them that they ought to do *themselves*. In the administering of help, whether it is money, food, or clothing, great care and good judgment are needed or you will do more harm than good. This poor man with a family, who sat down and actually shed tears because he could not find a job, could go to work and make garden *every day in the year* in that genial clime. Just now, October 3, he could plant potatoes, and get, say, \$2.00 a bushel for them, as I did last winter, or something near that price. He could do this as well as to do nothing. Do you say he has no ground? Well, he certainly can *find* ground near his home that he can work on shares; and just as soon as the people in that vicinity see him doing a man's work on a piece of ground, he will have a job with good pay, more or less.

My friend writes me this man has offered to work for fifty cents a day, and adds that nobody would give him any work, even at that price. Of course, I cannot say what the conditions are around Palatka, Fla.; but so far as I know, farmers and market-gardeners are complaining everywhere that the wages now demanded by competent men are more than they can afford to pay. Of course, there may be exceptional conditions on account of the war, and perhaps there

are times when factories are obliged to shut down, where, for the time being, there is a surplus of help; but the good energetic men or women who are ready to take hold of any kind of work never remain idle very long. What I have said about the high price of men's work will apply equally well to women. There is a continual complaint that the average help in the home costs so much nowadays that the good wife cannot afford it; and one of the worst troubles is, that the incompetent demand just as much as the expert help. Just one more suggestion:

The man or woman who goes to work with a sour face and her mind full of a feeling of the injustices that the working people have to bear, is not, as a rule, profitable help. It is impossible that it should be. But the cheerful or happy person who has pleasant feelings toward employer and all the rest of the world, including happy and pleasant feelings toward his Maker, is the one who makes a success in life, and is wanted and welcomed everywhere.

A few weeks ago a bright young man of foreign birth came here and wanted work. I spoke to our business manager, and he said our season was so nearly over we could not take on any more help—in fact, we should have to drop quite a few very soon. But the stranger looked so cheerful and good-natured, that I told him I could give him work for one day. I told him to cut down some trees that were dead and dying, and cut them up for firewood. I thought it would keep him busy all day. When he found out exactly what I wanted he went to work with such vigor and good nature that he had the job all done before noon. Then I found him some other work in the neighborhood, and he pleased every one of the neighbors. In a very few days he was wanted several times at once. One man especially who was laying stone flagging said he wanted the same fellow he had before; but the man was doing important work elsewhere, and could not very well be spared. When told of this he ejaculated, "Why, I *must* have that fellow. He knows just what to do without telling, and does it. He is worth two common men."

I presume the above incident could be duplicated in every community in the United States. If it is true, as my good friend has stated, that almost *half the people* in the United States are out of a job, it is a sad comment on poor imperfect humanity. But I feel sure it is *not* true. God forbid!

I fear my good friend *forgets* that even our government gets hold of some chaps every little while who use their positions

and authority to load up for their own personal use all they can get hold of from the government.

Here is something that has been going the rounds of the papers, and it seems that nobody can tell who originated it. It is a grand sermon, right along the line about which we have been talking—a sermon composed of only a single sentence. Read it, and see if I am not right.

If a man can preach a better sermon, or write a better book, or make a better mouse-trap than his neighbor, though he live in the woods, the world will make a beaten path to his door.

After the above was put in type our good friend from Palatka (H. H. Kollister) sent us a marked copy of *The Appeal to Reason*. In years past *The Appeal to Reason* has not "appealed" very favorably to me; but here is something in this issue that does appeal to my sense of right and wrong.

Help us to write into the Constitution of the United States: "War shall not be declared except by direct vote of all the men and women in the United States."

It occurs to me that socialism and Christianity can entirely agree and unite on the above sentiment, even if we cannot see things alike in other respects. May God hasten the day when war shall be declared in no nation unless the men and women vote for it. I say, may God *hasten* the day; for when that day comes that the *men and women* shall vote on the matter, *war will be no more*.

Our good-friend, at the end of one of his long letters, has this vehement winding-up:

The Devil rules the earth, and he'll starve me to death unless I serve him. But while I must do that now (at least to some extent), I warn him that I will bombard his forts with tongue and pen until not an atom of his profit system remains, and God's children can live that life which Jesus taught them to. Brother Root, will you help! God's kingdom come.

H. H. KOLLISTER.

THE A. I. ROOT CO.'S EXHIBIT AT SAN DIEGO; MOVING BEES SOUTH BY RAIL, ETC.

The following, from Howard R. Calvert, explains itself, and I am sure will be read with interest:

Dear Grandpa and Grandma:—I am not quite as far south as you are, but I imagine it is almost as warm here as it is in Bradentown.

Jesse Warren and I are getting along finely with the exhibit. There are certainly great possibilities out here in the West for our business. For instance, Jesse wanted some honey for his throat (he has some bronchial trouble), and we couldn't find any nice white honey *anywhere* in San Diego. At one or two stores they had a little granulated amber honey.

The climate out here is fine for beekeeping. Flowers and orange-blossoms are blooming all the year.

There are four fellows here in the Y. M. C. A. who are aviators. Two of them are flying for the

government, and two are in the aviation school here. I see them flying almost every day.

There are many poor people out here, thinking there would be work in connection with the exposition, while there is none. There are thousands of men out of work, waiting for the exposition to begin, with Christmas near, and nothing to eat or drink. Many of them came from San Francisco, where they could not get work either.

I enjoyed my last trip down to Virginia on the box car, even more than my first trip. We had an

oil-stove in the car, and cooked our meals. It was pretty cold nights, but we had plenty of bedding and newspapers under our mattress, and so we didn't suffer with the cold. When we got the bees to the new location I made a camp and built a "shack," and we had a fine time for a week while we were getting the bees arranged. I also put up a fence across one side of the apiary to keep the hogs out. I love to live outdoors that way, because I feel healthier, and always have a big appetite.

San Diego, Cal., Dec. 21. HOWARD R. CALVERT.

HIGH-PRESSURE GARDENING

POTATO-GROWING IN FLORIDA, ETC.

Last April I told you about my nice Red Triumph potatoes, and gave you some pictures. Well, on this New Year's day, 1915, it would be my delight to take the readers of GLEANINGS through our Florida garden. We have had the largest amount of rain down here ever recorded in November and December; and had I not learned by experience we could not have gotten rid of the wetness. Last April I told you how we buried the palmetto and underbrush, even when it was over our heads, and how we threw our whole garden up into narrow beds with deep walks between the beds. As our ground has a gentle slope toward the canal it was an easy matter to have all the water get away speedily down to the canal. In our book on potato culture I said we wanted, even in Ohio, both *under* drains and *surface* drains; and down here it is most emphatically true. When three or four inches of rain comes down in one day or night, the tile drains are too slow. In regard to the width of these beds our finest potatoes are where a ten-foot bed takes just three rows of potatoes—one in the middle and one three feet away (or a little less) on each side. Now, we don't want deep furrows *between* the rows of potatoes. It will work like wagon tracks in the highway, and the surface of the bed needs to be crowning, exactly like a nice roadbed or more so. It wants to be so the water will go off into the paths as quickly as possible, instead of running down hill *between* the rows of potatoes. Terry says in the A B C of Potato Culture that at one stage of the growing potatoes he had often wished he had a balloon to pull the cultivator so as to avoid the tramping of the horses' feet in the mellow soil. In that same book, in describing potato-growing on Jersey Island, the author says these people have the rich ground worked up so mellow a man can push his hand straight down to the elbow.

Well, Wesley and I have our dark sandy loam worked up in just about that way;

and now comes my "discovery" of a way to grow potatoes, or to *cultivate* them at least, without setting a foot on the soft mellow soil, especially when it is pretty well soaked with water. With my light sharp hoe I can work up the ground beautifully without setting a foot on the soft mellow soil, and I can break the crust and let in the air and sunshine when it is so wet it would be very bad policy to tramp between the rows. "Lots of work," do you say? Well, it is; but it is work that I enjoy more than I can tell you, and it is work that a man 75 or over can do when he isn't "much good" for any thing else; and, besides, I grow nicer potatoes than any one else around here has ever seen, and they go off quickly at a bigger price when displayed in our Bradentown groceries. Fertilizers? These extra-fine potatoes grow where we had a poultry yard several years. It is a piece of ground that has always been "most too damp and springy" for a garden; but with the tile drains and deep paths it just *suits* Triumph potatoes. Strawberries, corn, beans, etc., grow nicely in the damp mucky part of our garden. Sweet potatoes grow too much to vines; but on a dry sandy spot of poorer ground they give not only many more tubers but of much better quality.

UNRULY COWS, GARDENS, ETC.

Until recently cows have been permitted to "hold high carnival" on our streets nights; but since we have begun to call ourselves a "city," and have a daily paper, our marshal has begun putting the cows in the "pound," or at least some of them that had become "experts" in hooking gates open, etc., and it has made quite a little jangle. With this preface I submit a clipping from our Bradentown *Evening Journal*:

Editor Journal:—A good friend a few weeks ago told how hard it was to be fined and worried just because his cow happened to get through the fence, etc. Please let me "narrate" a little.

Last winter I was testing some choice sweet corn; and after a good deal of "nursing" and protecting,

the corn was almost ready to pick; but in the night a poor starved specimen of a horse was in our garden in the morning and had skillfully picked every ear (or bitten off a part), that was any good in the whole patch. Although he looked so helpless and inoffensive, he could use his heels with quite a little skill, as Mr. Rood can tell, for he called on pretty nearly all our neighbors.

Well, as you know, I am greatly given to hunting up "God's gifts," especially those adapted to Florida. I sent recently to California for seeds of the "winter muskmelon," a delicious melon that will stand as much cold as cabbages, at least the woman who advertises the seed says so; and if a woman said it, it must be true.

Well, we prepared the ground with great care, digging it up deep, and giving it plenty of manure

and fertilizer, and the melons were up and growing fine—at least they were yesterday. But this morning I found a cow had gotten in and waded the whole length of the bed, and then turned around and waded back again. We had fixed the soil so deep and mellow, she had a hard job of it.

Do you say we should have a good fence around our garden treasures (some of our trees cost several dollars)? But we can't well have a fence between us and our good neighbors. The women folks can't gossip real handy with any sort of fence in the way or a gate either. Bless you, no.

A. I. ROOT.

P. S.—Mrs. Root says I must explain that our neighbor has a good fence and gate also; but his next neighbor has a lot of boys; and, as you all know, boys will "sometimes" leave the bars down.

A. I. R.

POULTRY DEPARTMENT

POULTRY IN SOUTHERN FLORIDA.

Since early childhood there has always been a fascination to me about a hen and chickens, and also about a sitting hen. Who told her just how to go about hatching eggs? and how does it come that sitting hens for ages past have always followed the same program—a program that has puzzled and baffled incubator-makers, and is puzzling them still?

When we had been here about a week a hen wanted to sit; but as we had been getting only two or three eggs a day it took quite a spell to gather up 15 eggs. Down here I never use less than 15; and to our big Rhode Island Reds I give twenty or more. Just a word about the Rhode Island Reds.

I told you last winter we had two of these big hens to raise (or "mother") chickens. They are now over two years old; but when they are not wanting to sit they are always laying. When 70 hens gave only two or three eggs a day, these few eggs were quite sure to be yellow eggs, more or less. While the Leghorns and Buttercups were taking their long moult, these two were laying, say, about three eggs in four days, or an egg every day. Right here I am going to give you

A SUBSTITUTE FOR A TRAP NEST.

Trap nests are a bother, and take much time. Just pick out a hen you can tell by sight from the rest, and then see if you can not find some peculiarity about the eggs she lays. A hen of another breed from the rest, that lays a slightly different egg, can be easily "trap nested." Note down the day *she* lays, and you have it. Well, I reasoned if these yellow eggs bring 50 cts. a dozen, and the white ones, when the whole yard are laying (say in April) bring only twenty cents, why not keep more "reds" even if

they do eat more, especially as a large part of this "more" is green stuff that costs here little or nothing? Now let's get back to my sitting hen.

When she had twelve eggs I let her "start in," so as to have some new young chicks for my Christmas present—a present direct from the hands of a loving Father who taught the sitting hen her cute skill, and who moves *all* the machinery of this great universe. But I had only 12 eggs, and I wanted 15. I concluded just once more I would put in the other three next day, even if it is a bad plan.

HATCHING EGGS BY FLORIDA SUNSHINE.

I have long felt that we should, sooner or later, be enabled to do this, and now I will tell you how far I have succeeded in doing it.

The day before Christmas, every egg hatched (except the infertiles taken out the fifth day); and on Christmas, the chicks being lively, and wanting to get out in the warm sunshine, the hen came off, leaving two yellow eggs and one white one. I tried several times to push them under her when she brooded the chicks; but she seemed to choose a different place every time, and cared nothing for the three eggs. As I didn't want to fuss to keep a fire going for three eggs I let them go, placing them so the sun shone on them, until she settled down for the night. As none showed a pipped shell in the morning I again placed them on the bare ground in the sunshine. Well, in the afternoon I was delighted to see an egg pipped, and toward night the chick inside had got clear around so the shell came off in halves just as she settled down again for night. In the morning a great downy Rhode Island Red chick was running about, almost as lively as the rest. The next day the second yellow egg went

through the same program, and in the night the white egg hatched; but the chick was lost by my carelessness. Any way, I have two as fine chicks as any in the brood that came out of the shell by sun heat,* and right in bright sunshine. Now, how does this tally with the directions for all incubators, to avoid opening the incubator door when chicks are hatching?

Just one word more: The father of these red chicks is a full-blood Buttercup, or very nearly so; and already, at a week old, their wing feathers are out, embellished with the *beautiful* Buttercup spots and lacings. No gaudily painted Christmas cards can equal mine, for it was the finger of the loving Father who painted them *expressly* for my poor self.

I pretty nearly know by experience that some of my good friends will take me to task for "jumbling up Leghorns, Buttercups, and Rhode Island Reds;" but, my dear sirs, if I get eggs, and you don't, between Thanksgiving and Christmas, am I not ahead? The 303 eggs in one year came from a crossbred hen; and you *know* "handsome is as handsome does."

SITTING HENS—MORE ABOUT THEM.

In our issue for April 15, 1913, I described friend Stoddard's arrangement permitting the hen to stay right where she commenced to sit, and yet be free from annoyance from other fowls. As the arrangement necessitates expensive yards and nests, I have devised a plan that seems to answer about as well, and perhaps quite so. First, have all your nests in movable boxes, and boxes not all just alike. When a hen is found on the nest at night, go after dark and very quietly lift and carry box and all to some secluded place. A room or building for all your sitting hens is a very good thing. This room should have feed, water, etc., convenient for the hens; and my experience has been they will go back to their own box and eggs, after going off for feed and water. If they seem wild, be careful about scaring them off the nest until they get used to their new surroundings. Stoddard puts strong emphasis on the importance of letting the sitting hen run outdoors, fly and scratch, etc., and I think he is right. After a day or two I open the door of the sitting-room, and they always come back. During very warm days some hens will go off twice or more times in a day; and I have known some to stay from the eggs, when the day was very hot, for a couple of hours, and yet they made excellent hatches. One hen, in fact, was off when the eggs were hatch-

ing; but the hatch came off all right. When you carry the nest, hen and all, away, of course you fix a similar nest in its place for the other hens to occupy next day. No matter how many nests I provide, our hens seem to prefer particular nests, and one hen will stand and wait "her turn." The matter of a preference for the nest they were accustomed to was suggested when I tried to give a sitting hen a better box than her old rickety one. Although I fixed up the new box nicely, and put in all the eggs, she would get off and go back to the old familiar box, and I had to carry it clear off where she could not find it.

Hens usually prefer a nest up off the ground or floor. A couple of staples, such as are used for barbed-wire fence, driven in the edge of the box and hooked on two nails in the wall, will hold the nest secure, and yet it is easily lifted off the nails. To give the nest seclusion, and also to prevent fowls roosting on the edge of the nest, a thin wide board is fastened to the box for a roof, with so sharp a slant no chicken can stand on it. Now close *one* of the gable ends and it will please the "biddies" to a dot. A sitting hen, when safe from intrusion and prying eyes, often pulls the straw out of the corners so as to leave a place into which the eggs sometimes fall. To fix these corners so the newly hatched chicks cannot tumble down into them and get chilled, I fill them up with sandy loam. This the hen cannot well work out, and the damp earth is a good thing for the eggs, especially during a dry time. To put this in, without disturbing the hen, I use a big tinned tablespoon fastened on the end of a lath. This same tool I use to get the eggshells out of the way and to put a young chick back in the nest when it tumbles out. If you use your naked hand you may get thrusts of her bill that will bring the blood. This spoon is also handy in putting eggs under a hen when she is "fierce." I also use it in gathering ducks' eggs every morning when they lay in a concealed nest in the weeds and bushes. This same stick and spoon is also used as a "token of authority" when the flock of ducks seem inclined to disobey "marching orders."

DOSING SICK CHICKENS, ETC.

I clip the following sensible advice from a writer in the *Ohio Farmer*:

There are so many persons who are set on drugging fowls that a bit of general advice seems to the point. The best possible way to doctor sick hens with drugs is to make a hole in the ground at some convenient place and pour your drugs in the hole, meanwhile giving the hens sunlight, air, and good food.

What vexes me particularly is the adver-

* Sun heat is ample if we had some way of storing it up to carry the eggs through the night.

tisements in so many poultry journals of a long list of medicines at "50 cts. a box," when our different experiment stations have told us repeatedly that only two or three cents' worth of real medicine is contained in these little boxes. I hope the time is close at hand when the business of "robbing sick folks" by humbug testimonials (as well as sick chickens) is near an end. Precautions to keep out vermin are, of course, all right; but see you don't pay a great price for "insect powder."

When we arrived here Wesley assured me there was no vermin of any kind on the chickens or in the houses; but to be on the safe side I ordered a gallon can of zeno-

leum. Along with it I sent for a 25-cent box of insect powder, supposing I would get perhaps half a teacupful. I was pleasantly surprised to get a can with a pepper-box top, holding *over a quart*, and the directions on the can tell us to sift it freely where they wallow, and dust themselves under shelter. I did this, and the whole tribe, roosters and all, did the business of getting it most effectually all through their feathers. I didn't notice any "sneezing" among the chickens; in fact, it seemed just to suit them; but I did quite a little sneezing myself by the time I had sifted it into all their nests and around the roosts.

TEMPERANCE

PROHIBITION IN THE UNITED STATES, AND THE WAY IN WHICH IT IS PROGRESSING.

When you feel like saying, or hear some one else say, prohibition isn't making progress, just submit the following, which we copy from the *San Francisco Daily News*:

FOUR-FIFTHS OF U. S. IS "DRY;" NOT A SINGLE STATE ALL "WET."

ATLANTA, GA., Dec. 10.—Four out of every five square feet of the United States is "dry" territory! More than half of the people of the nation live under prohibition!

Such were the astounding facts submitted in reports to the Woman's Christian Temperance Union in convention here. To the layman who has viewed the white-ribboners' fight without interest the statistics are astonishing, and sufficient to convince the impassive voter that nation-wide prohibition is far more imminent than imagined.

Eighty per cent of the territory of the United States is "dry." Of the 2,973,890 square miles that go to make up continental United States only 737,828 miles are "wet." The remaining 2,236,062 are without saloons.

The last census gives the population of the United States as 91,972,266 persons. Of these, 54 per cent, or 48,118,394 reside in territory in which the sale of liquor is prohibited.

The winning of five States in recent elections gives the anti-saloon forces the majority. In September, Virginia adopted prohibition, and on Nov. 3 Arizona, Colorado, Oregon, and Washington were added to the list.

Now 14 States are totally "dry," and no States are totally "wet."

Pennsylvania, Minnesota, Montana, and Nevada, all mining and lumber sections, are the only States which have only minor prohibition areas.

In every other State the "drys" hold a territorial advantage.

In 1868 there were 3,500,000 persons residing in territory in which the sale of liquor was prohibited. In 1900 the number had increased to 18,000,000. In 1908 the number had doubled, reaching 36,000,000, and to-day it is more than 48,000,000.

The South has for many years been in the lead in the fight for prohibition. In 1907 Georgia passed a prohibition law, though not statewide. Within a year Oklahoma was admitted to the Union with a

constitutional prohibition against liquor. Alabama and Mississippi soon followed.

In 1908 prohibition was voted into the constitution of North Carolina. Tennessee followed in 1909. Alabama is the only Southern State which has dropped out of the prohibition column, doing so in 1911, by repealing the prohibition law and adopting a local-option measure. In 1913 West Virginia voted out saloons.

The prohibitory law had a close call in 1911 in Maine, where it had been in effect for 55 years. It was resubmitted, and was carried by a bare majority of 758.

The prohibition forces have met with reverses. They failed to win in Florida, Texas, Arkansas, Missouri, Colorado, and Oregon within the last four years, though two of these States accepted prohibition this year.

In two States which voted on the question this year, the proposition failed to carry. They were Ohio and California. The Ohio election was close, but prohibition was overwhelmingly defeated in California, probably due to the extensive wine industry in the State.

The following are the States in which the sale of liquor is prohibited: Maine, Kansas, North Dakota, North Carolina, Georgia, Oklahoma, Mississippi, Tennessee, West Virginia, Virginia, Arizona, Washington, Oregon, Colorado.

In the following States from 50 to 85 per cent of the population live in no-license territory: Alabama, Arkansas, Florida, Indiana, Idaho, Iowa, Kentucky, Louisiana, Minnesota, Nebraska, New Hampshire, South Carolina, South Dakota, Texas, Vermont.

WHY ARIZONA WENT DRY.

Among the manifold reasons which led the citizens of Arizona to cast their ballots for a dry State were the following which appeared in a column display advertisement published in the *Southwestern Stockman Farmer*, contrasting conditions in wet Arizona and dry Kansas:

"Last year," says this advertisement, "Arizona sent to the penitentiary at Florence 140 prisoners to each 100,000 population. Kansas sent but 16. Arizona's tax levy was \$4.95; Kansas' but \$1.20. Arizona had 1000 government tax receipts, while Kansas had but 104. If these represented saloons, Arizona had one for every 231 people, while Kansas had one for every 9050 people."—*Union Signal*.

Gleanings in Bee Culture

Photographic Contest

In order to keep in close touch at all times with what is being done by both the amateur and professional bee men and women in lines of beauty, as well as utility, we take pleasure in announcing another photographic contest, believing that the photographs will tell an eloquent story of a busy season of work among the bees.

We believe that no prize we could offer to the beekeeper would be so highly valued as a queen bee. We, therefore, offer a number of queens of our own stock, carefully selected for years for those qualities which are so valuable to the honey-producer, as well as queens from stock of other well-known breeders.

The territory covered in this contest is domestic, including Canada. The following rules will govern:

FIRST: The contest will begin February 15th and end July 1st, 1915. All photographs must be in our hands at the last-named date.

SECOND: Competition is limited to beekeepers or some member of the family. Entries may be made for as many different classes as may be desired, but a photograph entered for one class cannot be entered for another.

THIRD: Each photograph must be marked on the back with the name and address of the sender, with the class for which it is entered; a short description of about one hun-

dred words accompanying it and stating the conditions under which it was taken.

FOURTH: In judging the photographs the general appearance, neatness, convenience of the apiary, or exhibit, will be taken into consideration. Photos may be sent unmounted. We rather prefer them this way, and in a smooth or glossy finish if possible. We much prefer dark photographs. Of course, they must not be too dark.

FIFTH: All photographs and correspondence regarding the same should be addressed to Advertising Department, The A. I. Root Company, Medina, Ohio.

The Following are the Classes in which Entries May be Made:

Class A: Photo showing the most artistic arrangement, all things considered, of ten or less colonies of bees.

Class B: Photo bringing out possibility of keeping some bees even where stock or people must pass close by.

Class C: Most artistic and practical arrangement of any apiary of ten to one hundred colonies.

Class D: Best view of an apiary of one hundred colonies or over from a practical standpoint. East of the Mississippi River, including Canada.

Class E: Best view of an apiary of one hundred colonies or over from a practical standpoint, west of the Mississippi River.

Class F: Best view of anything relating to beekeeping.

Ten Prizes Offered in EACH CLASS are as Follows:

First: Select tested queen.

Second: Tested queen.

Third: Tested queen.

Fourth: Select untested queen.

Fifth: Untested queen.

Sixth: Select untested queen.

Seventh: Untested queen.

Eighth: Untested queen.

Ninth: Untested queen.

Tenth: Untested queen.

Queens for prizes first to fifth in each are from our own apiaries. The queens offered as prizes from sixth to tenth in each class are from other well-known successful breeders.

BE sure to rake the entrances of outdoor colonies clear of dead bees. If the entrance clogs the colony will die.

Queen-cage Candy Made out of Invert Sugar

THE ordinary queen-cage candy that has been used for so many years is a mixture of powdered cane sugar and honey, mixed into a stiff dough; but on account of the danger of carrying bee disease we have thought that we might use invert sugar instead, since boiling to prevent infection spoils it for bee feed as before explained. We have been making up some candy made with invert sugar, and so far it looks all right. If it can be used as a substitute for honey it will eliminate all possibility of transmitting bee disease in queen-cages.

baking purposes, namely, invert sugar. This is made by heating cane sugar with some acid—generally tartaric—to invert it. Of course, when invert sugar is cheaper than honey, it will be used by bakers very largely; but the sharp advance in the price of cane sugar or granulated sugar put invert sugar so high that bakers could not use it, and hence they have been going back to honey. As a general rule, invert sugar will be about a cent a pound higher than granulated sugar. When granulated sugar was 4 cents invert sugar would be 5 cents. Before the Great War there was very little honey of any grade that could be bought at that price, and hence many bakers were using the artificial product. The tables are turned (thanks to the war) in our favor now.

Winter Feeding and Breeding in Cellars

The Editor's Whirlwind Western Trip

ABOUT the time this journal is on its way, the editor will be making a trip through the great West. We will go to Denver to attend the National convention, and from that point we will move on to the great Northwest, taking in Idaho Falls and vicinity. From here we will go to Portland, San Francisco, Los Angeles, San Diego, Imperial Valley, Cal., we hear so much about; Phoenix, Arizona; San Antonio, Texas; St. Louis, Mo., and then on home, arriving at Medina about the 15th of March. It will be a whirlwind of a trip, but the object is to get data for GLEANINGS. We have not been through the West since 1901, and the result of that trip was to make material modifications of some instructions in our A B C and X Y Z of Bee Culture. Oftentimes a method or practice that will work in the East will not work in the West.

Honey for Baking Purposes

BEFORE the present war began there was an artificial product that was coming in as a sharp competitor of the cheaper honey for

A GOOD many of our subscribers have been skeptical about the possibilities of building up a weak colony in the cellar to a fair colony by spring. Some of our best beekeepers say it cannot be done. Some others believe that E. R. R. has allowed his enthusiasm to run away with his judgment. Still others aver that any and all kinds of feeding in the cellar stimulate activity: activity reacts, causing more eating, and overeating causes dysentery, and dysentery causes death. But, nevertheless, we have demonstrated that we have been able to do this kind of feeding, and cause the bees to breed and build up in the cellar. Mr. Rea, in this issue, page 150, shows how this is done. The bees in the cellar that have been fed since the 9th of January, and up to the present date, Feb. 10, have been breeding, are dry and clean, and show no traces whatsoever of dysentery. But it is important to have the candy right. Syrup or any liquid food will not answer. The candy must be hard enough and soft enough so that the food supply will come *regularly* and *continuously*. A candy that is not just right will spoil the whole thing. To be frank, we have

not been able to get it always perfect in times past. Mr. Rea (see page 150) has probably got it nearly right. If we can use a candy made with invert sugar without the employment of heat we shall feel that we have nearly solved our problem. More anon.

Our Cover Picture

WE always appreciate criticisms concerning the policies of the editors of GLEANINGS when they are sincerely given; and we are genuinely pleased, of course, when we receive an interesting word of commendation like the following:

Dear Mr. Root:—I have followed with much interest the long series of excellent and interesting photographs on the cover pages of GLEANINGS, and have marveled at your ability to secure a steady and constant supply of such excellent prints. I certainly hope this type of cover on the magazine will not be discontinued.

I venture to enclose a photo herewith which might possibly be used in this connection. It is a partial view of our experimental apiary, taken during the winter months. For this reason the hives are all shown as one-story, and only about one-fifth of the yard is within the field. This view was taken from the roof of the extracting-house, but is not nearly as good a picture as I had hoped for. You have no idea how difficult it is to photograph Spanish moss—unless you have tried it.

The photo also shows my method of numbering colonies, or, rather, hive locations, for I number the stand, not the colony or the queen. The one-inch numbers are stenciled on 1 x 4 x 22-inch stakes which are painted white. I have used this scheme for three years, and find it by far the most satisfactory of any yet suggested. The stakes are placed directly back of the centers of the hive-stands, where they are very convenient to hang the smoker on.

WILMON NEWELL, State Entomologist.

College Station, Tex., Nov. 26.

The Behavior of that Cluster of Bees behind Panels of Glass: the Essentials of Outdoor Wintering

IN our last issue, page 97, we referred to the fact that that cluster of bees mentioned in the previous issue had become disintegrated; that the protecting shell or wall had been broken, and that the individual members of the cluster were scattered, and many of them chilled to death. We also referred to the fact that the entire cluster was chilled through, and remained chilled for several days. It seemed as if the bees were dead, but after several hours they "came to" when placed inside before the radiator. We wondered at the time whether this freezing of the four days would have a disastrous effect. After the bees were warmed up they were uneasy, and showed unmistakable signs of dysentery, and in the space of four or five days they were all dead.

This goes to show that, when the cluster is too small, or the protection is inadequate,

there comes a time when the cluster loses its power to keep up its individual heat. When that time arrives the protecting wall or shell is broken. The bees become chilled through; and, even though a warm spell may follow, so that they revive, the severe chilling has a disastrous effect, apparently, resulting in dysentery and death.

We have broken into outdoor clusters in years gone by. Some seemed scattered all over the frames while other clusters in other hives were compact, and seemed to be in nice condition. But the first-mentioned bees always died in a few weeks' time. A broken cluster, then, in cold mid-winter is a very bad sign. It is evident that the bees are demoralized and the end is near.

The object-lesson from these observations is that a colony to be wintered outdoors should be strong or well housed. But even good housing (double walls and packing) will be insufficient to protect a weak colony outdoors. But weak colonies very often can be and are wintered in a good bee-cellar that is not too cold nor too warm, that has sufficient ventilation.

The Iowa State Convention; the Need is Education, says Inspector

THE third annual report of State Bee Inspector Frank C. Pellett, of Iowa, for the year 1914, has been published. Besides the short sketch of work accomplished by the inspector during the year 1914, the report contains information of value to the beekeeper in the care of apiaries and the treatment of diseases. The greater part of the pamphlet is taken up by the papers read at the third annual convention of the Iowa State Beekeepers' Association at Ames, Nov. 17-19, 1914.

The inspector found that, owing to the low production of honey and to the spread of European and American foul brood, both conditions due largely to the drouths of 1913 and 1914, many of the farmer beekeepers are either discouraged and going out of the business or are giving the bees the necessary attention and realizing consequent profits. The writer concludes that these adverse conditions have reacted favorably toward a more businesslike and scientific apiculture within the state. The greatest need is education.

The same conditions which favored the spread of the diseases made it difficult for the inspectors to deal with them. With inspection during a heavy honey-flow, robbing could be started easily, and the disease spread instead of checked. This emphasizes the need in certain localities of county in-

spectors who can work when conditions are favorable. At the same time the report recommends that the code be modified to give the inspectors more latitude in their work. As it now stands, the intricacies of the law are quite beyond the powers of the inspectors.

A further recommendation points out that, with funds which could be derived from taxing bees the same as any other property, research work could be carried on by the state agricultural experiment station and the information properly disseminated for the benefit of the beekeepers.

Among the papers submitted to the state convention and published in the report was a discussion of temperature and humidity in the wintering of bees by E. F. Phillips, Ph. D., of the national Department of Agriculture. This has been published in a Government bulletin, and was reviewed on page 71, Jan. 15. Wesley Foster, of Boulder, Col., presented methods of co-operative marketing of honey. L. H. Pammel's paper on honey-plants of Iowa calls attention to the values of the willows, the maples, the dandelion, the apple, plum, and cherry trees; the berries, the clovers except red clover, motherwort, catnip, heartsease, boneset, and goldenrod. Dr. Burton N. Gates, of the Massachusetts Agricultural College, adds force to a much-proclaimed truth in his paper entitled "The Value of Bees in Horticulture." L. A. Kenoyer reports entomological investigations among wild bees. C. P. Dadant furnishes a sketch of beekeeping from the dawn of man's recollection.

How to Make "Fondant" or other Soft Candy for Mid-winter Feeding

WE have referred to the desirability of avoiding the use of honey in making queen-cage candy on account of the danger of transmitting bee-disease—see page 4, Jan. 1. Elsewhere in this department will be found a statement concerning the making of candy with invert sugar, which, chemically speaking, is very nearly the same thing as honey. Others have been working on this problem of making bee-candy that will contain no possible germs of disease—notably Mr. O. F. Fuller, of Blackstone, Mass., and Dr. Burton N. Gates, of the Massachusetts Agricultural College. On page 435, July 1, 1913, we gave a brief review of an address by Mr. Fuller, on how to make bee-candy with glucose, or what has been technically called "fondant." During that time a good many inquiries have come in concerning it. As this is the time of year when possibly

some bees in winter quarters may be running short of stores, it is proper to consider how they may be supplied with food when no combs of sealed stores are available. Mr. Fuller and Dr. Gates have both said that the fondant such as they have described could be and has been used for winter food. In this connection we see no reason why queen-cage candy made by mixing invert sugar and powdered sugar together could not be used in the same way, as invert sugar contains no deleterious acids, and, apparently, it can be used precisely the same as honey in the making of old-fashioned queen-cage candy known as "Good candy." This is made by mixing sugar and honey (or invert sugar), and kneading it into a stiff dough. No heat is employed whatever in the process, and in this respect, other things being equal, it would seem to be much superior to the Fuller candy using glucose and a high degree of temperature. If there is too much or too little heat there will be trouble.

However, there has been so much call for information on the use of and how to make Fuller candy, or "fondant," that we have thought best to give a brief digest of Bulletin No. 7A, by Dr. Gates, describing it.

This candy, says Dr. Gates, has numerous advantages and possibilities. It is found to be a satisfactory stimulative feed; a feed for bees in transit, and satisfactory as winter stores. Colonies have been observed to leave natural stores for the candy. Some of the advantages claimed for the candy are the ease with which it is handled or supplied; the fact that it may be made in quantities, and stored until needed; failure to incite robbing; the ability to provision colonies with known amounts or weights, and its freedom from infection. There is no waste by evaporation or spilling, as is the case with liquid feed.

The candy may be made in any degree of hardness or softness, and may be stored for years if properly handled. It may be molded in pie-plates or feeders, or boards may be nailed to the side of a frame, and the candy poured and molded within the frame, allowing this to be hung in the hive adjacent to the cluster.

The latest recipe for soft candy is as follows:

- 12 lbs. granulated sugar;
- 1½ lbs. liquid glucose, or granular mixed with water;
- 1¾ quarts of water (equal to 40 oz., 5 cupfuls);
- ½ teaspoonful cream of tartar, added when the temperature reaches about 230 degrees F., or 110 degrees C.

Boil to 238 degrees F., or 114.4 degrees C.

The measures should be accurate. A

wooden paddle is superior to a spoon in stirring or beating the candy. A confectioner's thermometer is an advantage.

As soon as the sugar has begun to dissolve, prior to boiling, remove the paddle from the kettle, and do not stir while cooking. To do so will cause a coarse grain. Remove and cool to 125 to 130 degrees F., when the specified boiling-point has been reached. Then stir it vigorously until the mass appears in color and consistency like boiled starch or paste. At once pour into feeders and cool.

FINE-GRAINED CONTENTS FOR QUEENLESS CAGES.

Another way to cool the candy is to prepare a marble slab with bars of square iron, making a form. The candy may be poured upon the marble, and with broad putty-knives the mass may be beaten or worked upon the marble. This produces a finer grain, and usually a firmer and whiter fondant for use in queen-mailing cages or the transportation of bees.

By varying the boiling-point at which the candy is removed from the stove its hardness may be controlled. Furthermore, it should be boiled to one or two degrees higher on cloudy or gloomy days than on dry days.

STORING THE CANDY.

The fondant is best stored in a covered earthen crock which preserves the normal moisture. Over the mass should be placed a sheet of paraffin paper upon which is a moist cloth or towel. Queen-cage candy should always be kept in this way to preserve its consistency.

REMAKING THE CANDY.

If at any time the candy hardens it may be softened by the application of a few drops of water, and may be recooked by the addition of a small amount of water, and boiling as before.

Bees from the Akron Swamp Inclined to Show Dysentery

Our readers will remember that last fall we carried several yards of bees to points about thirty miles east of us, in the vicinity of that 1000-acre swamp—see pp. 570, 614, 702, 747, 791, and 920, last year's volume.

It will be recalled also that our bees gathered considerable aster honey. Mr. Halter who had them in charge mentioned the fact that colonies supplied with this food were inclined to show dysentery through the winter. There have been many other similar reports. It is not always that aster honey does this; but fearing that it might do so we moved most of the bees that had been reared in and near the Akron

swamps to Virginia. There were, however, about forty colonies that we kept at home for the purpose of experiment. The greater portion of these we put in our upper beecellar, and a part of them are showing dysentery already, and some are as good as dead. We are thanking our stars that we moved practically all the colonies with aster stores to Virginia, where they are having almost daily flights; for be it remembered that, when we examined these bees in January, there were no traces of dysentery.

GREENHOUSE FOR CURING COLONIES AFFECTED WITH DYSENTERY

For the purpose of experiment we are placing some of these colonies that have dysentery as a result of the aster stores in a small greenhouse in the hope that we can save them.

Early last winter we had one colony showing slight signs of dysentery. This we placed upstairs in our office building, in a warm room. In front of it, to catch the flight of the bees, we placed one of our regular wire-cloth cages that we use when a colony is attacked by robbers. This is 4 feet long, 2 feet high, and 2 feet wide. Many of the bees actually did fly out into this and discharge their feces. Some of them returned, but the most of them worried themselves on the wire cloth and died. There must be a couple of pounds of dead bees lying on the floor of the cage. Examination of the hive this morning, Feb. 10, showed quite a cluster of nice bees; and although this colony has been in a warm room continuously it shows no signs of dysentery. As a cure for the malady it worked well, but as a wintering proposition it can hardly be called a success.

But possibly a cage like this may be used, or, better, a greenhouse, to let some colonies from the cellar afflicted with dysentery clean up in the absence of any warm flight days. We will give our readers a little later the benefit of our experiments.

By the way, our bees, with the exceptions noted, some 300 colonies, are wintering nicely in our cellars.

Oh, yes! another exception should be noted; and that is, that bees for exhibition purposes that have been on display in the windows of drugstores and groceries to advertise honey are practically good for nothing when brought back. These were put into the cellar, thinking we might save them; but the general disturbance and excitement of several days of exhibition got them so demoralized that they kept on with their uneasiness until they all died off. We have concluded that exhibition bees, after they have served the purpose of advertising, are practically a total loss.

Dr. C. C. Miller

STRAY STRAWS

Marengo, Ill.

C. F. BENDER writes: "My experience is different from that of Mr. Herrod, p. 5. I have always put away my extracting-combs wet, and have had much trouble with moth larvae."

I. E. FIELD, when I cage a queen in a mild case of European foul brood I do nothing whatever with the brood—just leave it, and in most cases the bees will clean it out when it dries up.

F. M. BALDWIN calls for experience as to introducing queens by daubing with honey, p. 67. That plan was common 50 years ago. As little has been said about it lately, I suspect it was not always successful.

JAMES D. BENSON, p. 82, when a colony swarms, kills cells, and puts "back four or five frames of brood in an eight-frame hive." In other words he replaces three or four frames with foundation. I should expect my bees to swarm again within 24 hours.

D. E. LHOMMEDIEU, p. 125, objects that Miss Wilson let the bees be queenless a day before smoking in the new queen, and says the queen should be smoked in just as soon as the old queen is caught out of the hive. But that's not according to Arthur C. Miller, friend Lhommedieu, who says the bees may be queenless any length of time.

"It is suggested . . . that a smoker be held" at the Denver convention, says the program. Is that suggested by some one who doesn't know that few beekeepers use tobacco, or has there been a deterioration in late years? [Some of us who do not use the weed might use a bee-smoker filled with greasy waste; then we can all "smoke."—Ed.]

T. MAGUIRE, *Beekeepers' Gazette*, 120, says: "Last May we had, perhaps, the most severe frost in living memory, and, notwithstanding this, we had also one of the finest crops of fruit gathered for a long time. . . . But, again, in certain seasons a slight frost seems to kill off the blooms." In the latter case he thinks the frost is not to blame for the loss of the crop, but the persistence of cold winds which prevent the bees from flying. He is likely right in thinking that few realize the full value of bees to the fruit crop.

J. L. BYER is quite right, p. 97, that sometimes one may better his chances for wintering bees by moving further north. Not only snow, but wind, makes a big difference. I'd rather take my chances 200

miles north of Marengo in a still place than to stand the piercing prairie winds here. [We agree with you and Mr. Byer; and we also agree with you that a spot protected from high winds is much better for bees wintered outdoors than a place that is exposed. We are beginning to believe that bees in single-walled hives in a protected location are better off than in double-walled hives in a place where fierce piercing winds can strike them. Of course it is better to have both the double-packed walls and the protection from winds.—Ed.]

WESLEY FOSTER, p. 98, like J. G. Brown, wants me to substitute something else for white clover in this two-for-one-ready-for-the-clover-harvest business. Not on your life, Wesley. White clover is what I was talking about—not sweet clover, alfalfa, buckwheat, nor any thing else. You say you can increase your crop of white sweet clover by early dividing. So can I—at least I think I can—right here in Illinois, without going to Colorado. I notice you specify *white* sweet clover, which, I suppose, means you want to leave out yellow sweet clover, which comes earlier. Now I wonder if you Colorado fellows realize that white clover comes still earlier than yellow sweet clover. Last year I noted the first white-clover blossom May 27, and the first white-sweet-clover blossom June 23, just 27 days later. (The harvest begins about 10 days later than the first blossom.) That, you see, gives my bees, and I suppose it does yours, 27 days more to build up for the white sweet clover, and that 27 days is enough to make all the difference between success and failure. You say the two colonies build up steadily during June, ready to store surplus July and August. Yes; but while they're building up in June, two or three weeks of the best of the white-clover flow is on, and I've known the harvest to cease July 4. In 1913 the flow continued late—I don't know just when it did stop—and it is just possible I might have gained by dividing; but 1913 was one year in fifty. Now please let's understand each other. I don't object to the Alexander plan of increase—it's good. I do object to telling the beginner that he can divide by the Alexander or any other plan and have two good strong colonies in place of one ready to commence—not to work on the fag end of, but to commence—on the clover harvest. He'll get left nine times out of ten if not ninety-nine in a hundred. I'm ready to be shown, but that's my honest conviction.

J. E. Crane

SIFTINGS

Middlebury, Vt.

I agree with J. L. Byer, p. 928, Dec. 1, in thinking a ten-pound pail the cheapest and most convenient feeder we have.

That method of ridding combs of bees for extracting, as given by Geo. Shiber, p. 988, Dec. 15, is well worth remembering, saving, as it does, all brushing, and then making new colonies of the bees carried into the extracting-room.

Mr. Doolittle tells us on page 887, Nov. 15, how a buyer says he doesn't care for the color of sections—it is the honey he is looking at. Just so. And if it is in sections a little off color, then honey that is a shade off looks better than in white sections.

"Honey-fizz" at the Connecticut fair at Hartford is another "new idea" surely. Well, when this new, non-alcoholic, refreshing, pleasing, and healthful drink takes the place of the enormous amount of beer now sold there will be something for us beekeepers to do in supplying the quality and quantity of honey required for this purpose.

On page 920, Nov. 15, Mr. Hardy tells how his beets averaged 19 per cent sugar. If we compare this with the average per cent of sugar in beets one hundred years ago we shall find it almost exactly three times as great. I fear few of us fully appreciate the wonderful improvements that plants as well as animals and even bees are capable of.

A. E. Crandall, page 843, Nov. 1, tells of the pleasure of a trip with a "bee inspector" down in the Nutmeg State. I have no doubt of the truth of his statements, but I want to call attention to the fact that it gives the inspector quite as much pleasure to take an intelligent beekeeper along with him to discuss the strange ways many people have of keeping bees and the hives they use. Some of the most enjoyable days I have spent in inspecting bees have been of this kind.

Those pictures of the new apiarian laboratory for apicultural investigations under the United States Department of Agriculture, found on page 856, Nov. 1, and the cover page of Nov. 15, are of more than

usual interest, and we may all rejoice that we have such a home for this division of the entomological section of the Department of Agriculture. We may also rejoice that this line of work has been so ably and vigorously prosecuted in the last few years, and that it is likely to be of even greater value to us in the future.

Attention is called on page 833, Nov. 1, to the large amount of money offered at the Hartford fair for prizes. This comes of the Connecticut idea. A teacher once asked a small boy how the Connecticut River came to receive its name. The boy replied that it was because it connected Vermont and New Hampshire and cut through Massachusetts. Now the Connecticut State Beekeepers' Association has been in the habit for several years of connecting up with the Charter Oak Fair Association, which holds its fairs at Hartford, by putting up as much money for prizes as the fair association will, which has of late amounted to \$500 per year. Then the beekeepers' association selects a judge for the bee and honey exhibit, and the fair association pays his expenses, and he cuts up the \$500 into premiums and divides it among the beekeepers—Connecticut—don't you see? Not a bad idea for other State beekeepers' associations to follow.

FEEDING GRANULATED HONEY IN THE SPRING.

In a footnote on page 941 it is stated, "Candy is about the only substitute for good sealed stores we can use in the dead of winter." Beg pardon; but I fail to see why honey granulated solid is not just as good. It is even softer, and I have no doubt more easily taken or liquefied by the bees. It is true that bees will sometimes reject coarse granules of honey; but it is not often the case, and may come from the weakness of the colony; but the loss from this source has never been large. I have even laid combs of honey granulated solid over a good colony and have them remove it, and so save the combs and feed the bees at the same time. Indeed, I have at the present time a lot of sections candied solid that I have laid away for spring feeding. The ease with which bees can be fed in the spring with granulated honey is surprising. You can feed at any time of day, as it doesn't excite them as does liquid feed. The experience of T. P. Clare, page 987, Dec. 15, is of value along this line.

BEEKEEPING IN CALIFORNIA

P. C. Chadwick, Redlands, Cal.

To-day, Jan. 28, we are in midst of the heaviest rain of the season.

Dr. Miller says, page 7, Jan. 1, "Really, one great beauty of beekeeping is that you never get to the end—always something more to learn." This reminds me of the following quotation:

Learn as though you expect to live always;
Live as though you expect to die tomorrow.

The remarks of the C. C. Clemons Produce Co., page 37, Jan. 1, are sound and of importance. Wesley Foster also covers about the same ground. The marking of honey in the individual amounts should be as near the exact weight as possible. Then the customer knows what he is getting and is willing to pay for the amount received. But, as Mr. Clemons says, when a section is stamped eight ounces and actually contains thirteen, it is not easy to persuade the buyer that he is getting long measure. The American people are not used to long weight, and are likely to look with suspicion on any one who is so un-American as actually to give something away. Mr. Clemons has been in the honey-market for many years. I have been in his establishment when it was known as that of Clemons & Cloon; but later the name was Clemons & Mason.

This year I marked all of my cans with a small label, which read, "Guaranteed sixty pounds net." When filling my cans I set the scale to balance at one pound in excess of the sixty pounds called for. In this way I kept well within the law, felt well satisfied with my measure, and suffered no great loss.

In commenting on the last item, page 7, Jan. 1, the editor in speaking of destroying foul-brood combs uses the word "burn." If there is any word that can be found that grinds my nerves in connection with the eradication of foul brood, it is that word *burn*. I wish for the sake of those who have had their bees destroyed by fire, simply to accomplish the same results that might have been accomplished by hot water, the word *burn* had never appeared in connection with the treatment of disease. A few years ago one of our county inspectors made the assertion before the state convention that he had burned a number of perfectly healthy colonies because they had been shipped into

his county contrary to a county ordinance. I am hoping that I may live to see the day when we shall have a national law regulating the transportation of bees, thus eliminating all state and county ordinances. County ordinances may be all right in the hands of an inspector who can maintain his good judgment after having become an official (if he had any to start with); but with the chances involved the risk is too great. Many of our county ordinances are principally used as a fence to keep other bees out. In at least one instance of which I know, an inspector from another county inspected a shipment for Imperial Co. which he accompanied in person to that county, and they "stuck." Others have been turned back.

California beekeepers should not be misled by the discussion of the A. Swahn letter by Dr. Miller, p. 979, Dec. 15, and J. G. Brown, p. 27, Jan. 1. I consider the argument of Dr. Miller sound as affecting the greater part of our state, and I believe with him that Mr. Alexander's situation was one in a thousand. There are places in the alfalfa districts of the Imperial Valley, as well as some parts of the San Joaquin, where the harvest might be increased by an early division of colonies. But as a rule in the greater portion of the state—in fact, the entire nation, the practice would be detrimental rather than beneficial, so far as increasing the quantity of surplus honey would be concerned. I infer that Dr. Miller believes in one large force of bees to a hive rather than a slightly greater number divided into two hives, and in this I believe he is entirely right. There is no doubt the Alexander plan will work in a few localities; but in most parts of our state, as I have said, it would accomplish very little for the increase of the crop of the same season. I never figure the increase of colonies in the results of my season's crop. If they are increased by natural swarming, the loss as a rule to the parent colony will more than offset the gain from the swarm; but if by dividing, the gain of both will as a rule not equal the loss of the united colony. So my plan is to figure so many colonies spring count. I have never seen a colony so strong that I thought it would be better divided, or would produce more in two hives. Give them room according to their strength and they will do the rest.

BEEKEEPING IN THE SOUTHWEST

Louis H. Scholl, New Braunfels, Texas.

About ten years ago I called the attention of readers of GLEANINGS to the importance of removing as much drone comb as possible from the hives during spring inspection of the colonies, for the reason that it was expensive to leave it. I am still of the same opinion, and give the same advice. Too many beekeepers even to-day allow a great deal of the drone comb to remain in their colonies. It means the rearing of a host of useless consumers at a great expense, and aids in the decrease of our profits. Cut it out!

NEWS NOTES AND PICTURES WANTED.

I should appreciate hearing from the many beekeepers, throughout the Southwest in particular, and over the rest of the state in general, during the year. Photographs of apiaries and other things pertaining to beekeeping will be very welcome. It has been my desire to show up in picture and pen more of Texas beekeeping for a number of years; but it has been almost impossible for me to get out and visit the many beekeeping friends, and snap them and what they have and the things that they do, as I have wished. To make a beginning in this direction of "exposing" some of the big things that are in Texas, and the things that are being done here, I shall be exceedingly glad to get a large number of such pictures and news notes as will be interesting to the readers of GLEANINGS. Due credit will be given in all instances, and, if desired, pictures will be returned when so instructed.

TEXAS BEEKEEPERS, TAKE NOTICE.

The legislature of Texas will have been in session quite a while before our readers get this issue of the journal, but not so long as to have arrived at the measures providing for appropriations for the many things that legislatures are usually called upon to provide for. A request for an appropriation will have been made by the Agricultural and Mechanical College and the Experiment Station for a sum of \$10,000 for the Department of Entomology, most of which amount is to be used for foul-brood-inspection purposes. The request has not yet been filed, so that I am unable to know its exact nature, other than that this amount is asked for, and that the beekeepers are expecting that the greater portion of it will be used

for foul-brood work. In any event, it is important that the beekeepers show their interest in this important matter by either seeing their respective representatives in both the House and the Senate, or writing to them at the earliest opportunity if this has not already been done.

It is very necessary indeed that the members of the legislature be informed as to the needs of the beekeepers so that they may know what is wanted. There has always existed, in the minds of most of the beekeepers and others, that erroneous impression that these men do not pay any attention to such letters from their constituents. I am frank to say that I was at one time guilty of the same belief. Of later years I have been led to change my opinion, because I have associated more or less with these "fellows," and now, since I am a member of the legislature myself, and have learned to know what goes on in such a law-making body, I have found that the members not only do read these letters but consider them, and are desirous of lending a helping hand if they can only know more about the nature of the request.

Of course, I feel that I can be of much help now that I am a member of this body, and I feel that the beekeepers are depending upon me to do my share. Even at this time I have been able to give much information on the subject in question to many of the members who did not understand the matter in the least, and I have already laid plans by which I feel that the measure will be fully understood, and that there will not be any trouble about passing the appropriation measure.

If I can get the additional assurance from the beekeepers that they will inform their representatives I see no reason why we beekeepers of Texas should not be dealt with in a most favorable manner. As I have indicated in many former instances, when matters of such importance were up it is exceedingly important for the beekeepers to do their share of duty, and then, and not until then, can they expect the "other fellow" to do his. For this reason I again hope that, in case the matter has not been reached in the mean time (and I do not think it will be reached during the regular session), every beekeeper will make it a point to inform his representative why we want this money, and that we must have it to protect our industry from which we make our bread and butter.

CONVERSATIONS WITH DOOLITTLE

At Borodino, New York.

POLLEN AND PROPOLIS.

"Mr. Doolittle, I read in GLEANINGS something about bees requiring pollen in order that they might thrive. What is pollen?"

"Pollen is the farina or fertilizing dust from plants and trees necessary for the perfect fruiting of each separate species. This dust is finer than any miller can produce. When the season is late, or pollen is scarce in our locality, bees will take flour, meal, or finely ground oats in lieu thereof. In many localities bees are thus fed in the spring till the pollen-bearing flowers open."

"How do bees gather any thing so fine?"

"If you will examine with a lens one of the hind legs of a worker bee you will find that the stoutest joint is very square-shouldered at the hinge, and that this hinge is well over toward the side of the leg, away from the body of the bee. These shoulders form a pair of jaws, as it were, which open when the leg is bent and close when it is straightened. The upper jaw has a row of spines which strike on a plate on the lower jaw, and thus the bee can use force enough to hold and manipulate things to an extent which seems quite marvelous. In the gathering of pollen these shoulders or jaws are called 'pollen-baskets' because they are used for holding the pollen as it is gathered. And the bees often heap these baskets full to overflowing with the loads they bring in from elm, hard maple, and other flowers which are abundant pollen-producers."

"And that is what the bees are carrying when they go running in the hives with 'yellow legs.' Years ago I heard it said that such loads were wax; but I always doubted it."

"Wax is not gathered, as it is not an extraneous substance which needs only to be collected for use."

"But how does the bee cause such minute particles of pollen-dust to stay in those baskets?"

"I do not know that I can answer that question; but from what I could observe by lying down close to a feeder having finely ground oats in it my conclusions were that the bee, when going out in quest of pollen, always took along a little honey in its honey-sac, unless pollen was being gathered from flowers which produced both pollen and nectar. After the bee had rolled about in the flour and taken wing, she seemed to

touch her front feet to her mouth, then rub them about on her dusty body, when the dust which adhered to those feet was transferred back to the next pair of feet, when these in turn were drawn, or partially so, through between the spines and joints spoken of before, which left the now moistened pollen adhering to the pollen-baskets. And thus, by a series of extremely rapid motions, the baskets would be seen to become fuller after each dip and roll-over the bee would take in the oat flour. I have seen this manipulation of pollen nearly or quite as well when the bees were at work on the dandelion. But to get any thing like a correct view the head must be lowered so the bee will be between the eye and the sky."

"And what is the pollen used for?"

"It is taken by the nurse bees, together with honey and water, and, by a sort of individual home manufacture, formed into chyle (similar to that used by the mother pigeon in preparing the 'milk' with which she feeds her young), when it is fed to the larvæ, on which they thrive. No larvæ can be matured without pollen, or something as a substitute. Bees gather only one kind of pollen at a time. While different bees may carry in several colors at the same time, the pellets on any one bee will be all alike."

"Now a few words about propolis. Is that gathered from flowers?"

"No. So far as I know, nothing in the floral line, after opening, gives off propolis. The milkweed flowers are somewhat sticky, and from their peculiar shape often trap the bees which work on them, and hold them fast till they die; but I have never detected bees at work gathering propolis from these flowers. It comes mainly from resinous buds just before they expand, or from the buds which are forming for the next year's growth—mostly from the buds of the balm-of-gilead, in this locality, during August. In the spring they will often be seen collecting it from old hives left standing in the sun, so that it becomes again soft enough for manipulation."

"What use do the bees make of such sticky material?"

"It is mostly used for coating uneven surfaces, and filling up cracks about the inside of the hives or whatever their home may be. It is also used in hermetically sealing up any offensive matter that may be too burdensome for them to remove."

GENERAL CORRESPONDENCE

ANSWERS TO QUESTIONS ON OUTSIDE WINTERING

BY R. F. HOLTERMANN

When giving the methods of wintering outside as practiced by me, in the first place I plainly stated that, so far as the cases and fence are concerned, I learned the method from Jacob Alpaugh, and it appears to me that we should not lose sight of that.

From letters I have received, and from the cover picture in GLEANINGS, Jan. 15, it appears necessary to draw attention to the too frequent way of following (or, rather, *not* following) directions.

If the reader will look at that cover picture he will see that the result of having those covers placed against the winter cases is to bring the snow which has fallen immediately under the entrances up to the hives or cases. If there had been a heavy fall of snow the snow would even block the entrance. Now, to this latter I have no particular objection so long as the snow is removed as soon as a thaw sets in, which would not likely be the case if the beekeeper did not look after the bees during the winter. But such a situation has far worse results. I pointed out in my writings that wherever ice or snow is immediately under the entrance the effect is to chill the bees; and as they fall on the snow or ice they perish. To illustrate, vessels on the Atlantic in the dark are at times able to detect the proximity of icebergs by a fall in temperature. If the temperature in the open is 55 or 60 degrees when the bees fly, the temperature one, two, or three inches from a block of ice would be much lower. The bees flying from the entrances in the illustration might not have perished had the cases been set on blocks nine inches high, and had the snow been, as it would have been in this case, a foot from the entrance. Of course the bees may have been dead ones cleaned out.

Some ask if the small round entrances (three or four $\frac{7}{8}$ -inch holes) are sufficient. All I can say is what I have said. I have cut the wood away at times between two of the holes. Otherwise they have answered the purpose. When beekeepers undertake to enlarge materially and permanently the entrances they do so contrary to the system I use. Again, with a board slanting upward directing the flight to the entrance, the current of air into the entrance is intensified, which in windy weather would be very undesirable.

The illustration on page 61, Jan. 15, shows a full-width entrance with a full-width bridge instead of an entrance 5 inches wide by $\frac{3}{8}$ inch deep, with three $\frac{3}{8}$ -in. holes just under the front board of the hive, as I have them. My method gives much less entrance room, and makes the hive much less liable to be robbed. In fact, there is a vast difference in this respect.

Next, some have not left an opening at the top of the case to allow the air to pass over the packing and carry away the moisture which comes from the bees through the packing. Any one reading my articles will see that I pointed out the necessity of having a $\frac{5}{8}$ -inch hole in the sides of the case and immediately under the cover.

The packing should be of such a quantity that there is an inch or two of space between the packing and the cover, allowing a free circulation of air between. If this is not done, there will be a tendency for moisture, expelled by the bees, to linger about them.

Again, many beekeepers make the cases out of $\frac{7}{8}$ -inch lumber instead of $\frac{1}{2}$ -inch or $\frac{3}{8}$ -inch. It is not a question of price or convenience. I am not going to say that bees cannot be wintered, and often well wintered, in $\frac{7}{8}$ -inch cases; but the object in the thin case is to have the heat of the sun is painted a dark color, as was recommended.

is painted a dark color, as recommended.

In carrying on experiments with living things one must be very careful to have all the conditions accurate. To compare certain details, all the other conditions must be alike. This is very difficult to obtain in animal life; and to cover these imperfections one must repeat the tests again and again, and then draw conclusions from the general average of results.

It requires a judicial frame of mind to carry on research work.

My advice is to have shade in the apiary. Fruit-trees leaf out after the cold spring has passed, and therefore, in my estimation, they make a good shade. Have the apiary in a sheltered place. One man in the state of New York recently told me that he was going to locate his apiary on top of a high hill at the north end of a lake. The location may be the ruin of his apiary so far as

profits are concerned. On top of a hill is not a good location unless well sheltered by trees.

I have also had a number of letters from beekeepers about fences.

Several ask about combs melting down in hot weather if there is a fence about the bees. We have had a temperature in the shade of 96 degrees. I have never had any

combs melt down; but I have an entrance to my hives $1\frac{1}{8}$ in. deep by the width of the hive. I do not know what I might have had with an ordinary entrance if I could imagine myself foolish enough to use one. Build your fence so you can take out every second board in the summer, and plenty of air will pass through the apiary.

Brantford, Canada.

THE EDITOR'S PLEASURE-TRIP DOWN THE INDIAN RIVER, FLORIDA

An Interview with O. O. Poppleton, the Famous Bee-king of Southeast Florida; the Long Idea Hive

BY E. R. ROOT

I was unable to finish my Florida articles last spring owing to the lateness of the season; so I decided to defer the publication of the remainder till the following winter, when the thoughts of all beedom are again turned toward Florida and the Southland generally.

Last winter, while visiting with my parents in Bradentown, I received a letter from Mr. W. A. Selser, from his home in Florida, on the east coast, where he goes every winter to recuperate. In this letter he referred to our projected cruise down the southeast

would fish and gather oysters on the way. It is not necessary to go into further details; but the result was that Mr. Selser chartered a cruiser from his neighbor, Capt. F. S. Slifer, or Dr. Slifer, a specialist of Philadelphia, who was also spending his winter in Florida. The doctor had never cruised down among the Keys, and was willing to take our party for a very moderate sum.

We started from Stuart about the 10th of March, last year, with a good supply of eatables and a cook aboard—one who knew

FIG. 1.—The 40-ft. gasoline cruiser in which the editor of GLEANINGS and party cruised up and down the Indian River and inland waters of the southeast coast of Florida, studying beekeeping conditions.

coast of Florida, and he was particularly anxious that Mr. G. M. Gray and his wife (who were with me on the trip) should go along to make up the party with him and Mrs. Selser. As I had covered a portion of the east coast *northward*, Mr. Selser's general proposition, as may be surmised, was very attractive—especially so as he said we

how to do things up right. See Fig. 1. I enjoyed drinking in great drafts of seabreezes, for I had been sick with chills and fever; but Mrs. Selser said she was going to cure me of all these, and she did. She put me on a diet of fish and eggs, oysters, grapefruit, and oranges. The two last mentioned were served five or six times a

FIG. 2.—O. O. Poppleton standing beside one of his Long Idea hives in Pompano, near Miami, southeast coast of Florida.

day. I had not been long on this trip before my chills disappeared, and I began to build up. A cruiser trip and a genial company aboard will cure almost any sick man. It certainly put me on the high road to health; and I have been comparatively well ever since.

Speaking about grapefruit, I have now "acquired the habit," and a good habit it is. Instead of using the more solid foods I now use the lighter acid fruits such as apples, grapefruit, and oranges with just enough of the proteins to make a balanced ration. Thanks to Mrs. Selser, who did more for me than all the doctors I ever employed, I am beginning to know *how* to live.

Our trip comprised a cruise of some 250 or 300 miles down the Indian River and some smaller rivers. We could stop and eat and sleep anywhere at any time. All we had to do was to cast anchor in the lee of some cape or island. There were no hotel bills to pay; for we could eat and sleep on the boat or go ashore any time we pleased.

When we ran out of eatables we went

ashore and bought at the groceries as cheap as any one. At the end of our trip we divided up the expense, which, outside of the cruiser, was no more than if we had been at home.

At Pompano, on the way down, we picked up Mr. O. O. Poppleton, the "Florida bee-king," whose headquarters for the last ten or twelve years have been Stuart and Miami. Mr. Poppleton has, during all these years, sailed these waters back and forth until he knows them perfectly. His knowledge of the shallow places was invaluable.

At Delray we picked up Charlie Repp, of the Repp Brothers of New Jersey. I have already referred to the interview with him. He is the famous apple-grower, and one of the great friends of the honey-

bee. See GLEANINGS, May 1, 1914, p. 347.

POPPLETON LONG IDEA HIVE.

It will be my purpose this time to tell something about Mr. Poppleton, one of the pioneers of beedom, who has passed the threescore-and-ten mark by one year, and who to-day bridges the days between Langstroth and Quinby and the present time. Mr. Poppleton was a successful beekeeper in Iowa away back in the early days. He was one of the very first to discover the value of packing and double-walled hives for wintering bees. He used the Long Idea hive of 24 American frames away back in the early days, and has continued to use it throughout all the years since.

Some years ago ill health compelled him to go to Florida, and he, like the rest of us, found there "the fountain of perpetual youth." Although he is now past 70 years of age, he is a man who is remarkably well preserved, and his mind is as clear and strong as it ever was. I counted it a great privilege to spend several days with this man on board our cruiser, where I could

interview him; for he remembered that Mr. Poppleton was for a number of years the greatest migratory beekeeper in the world. While his operations in this line were not, perhaps, conducted on as large a scale as those of the Root Co. during 1914, yet he carried on the business on a large scale a long time successfully.

Occasionally we used to get little items as to what he was doing. Every now and then there would be a picture of his bees on a gasoline-launch; but beyond these and some very short items about his migratory beekeeping, the bee-world has not seen much of him. The fact that he belongs in the list of old veteran beekeepers alongside of Langstroth, Quinby, Tupper, Gallup, Wagner, Heddon, Hutchinson, Miller, and Root makes him all the more interesting. Of this number there are only two others besides Mr. Poppleton who are still alive.

Some forty or more years ago the merits of the Long Idea hive were extolled in the columns of the old *American Bee Journal*, and, later on, in *GLEANINGS*. This hive primarily consisted of a single brood-nest capable of holding 24 American frames, 12 inches square outside. It was always used as a single brood-chamber, never on the storifying or supering-up plan.

The hive that Mr. Poppleton uses, or did use up to a year ago before he sold out, has a brood-nest or hive-body 40 x 13 inches deep, by 13 wide, inside measure. This will take 24 closed-top American frames, 12x12 outside measure. While these dimensions would seem to afford a rather large beespace for a 13-inch hive Mr. Poppleton was doubtless figuring on the accumulation of propolis and irregularities of construction; for it would have to be made at a regular planing-mill or by a carpenter, as no supply manufacturer makes it. The cover telescopes down over the hive proper, leaving

FIG. 3.—O. O. Poppleton manipulating one of his Long Idea hives at Stuart, Florida.

room in the top for a cushion or packing material if necessary. The body is cleated at the top end and sides to make it convenient to handle. In the illustrations accompanying (Figs. 2 and 3), the general style of the hive will be seen, together with the frame, with Mr. Poppleton standing at one side.

One would think, to look at this hive, that it is about the most unwieldy, clumsy, and awkward thing that could possibly be used for migratory beekeeping. It would seem to be especially so for a man past 70. I have actually heard many persons say, even in Florida, "I do not see how such an intelligent man as O. O. Poppleton can get along with such a monstrosity." Such remarks came even from beekeepers not far distant from him. I must confess that I myself could not see any merit in it; but after having heard Mr. Poppleton explain the hive and system as he uses it I am not sure but I should like to work with it. Indeed, it may be better for migratory beekeeping than any hive of smaller dimensions

FIG. 4.—Mr. Poppleton's gasoline-launch which he used in his migratory beekeeping on the southeast coast of Florida. This launch was capable of carrying about 50 Long Idea hives at a time, besides bedding and cooking appliances. In the height of the season Mr. Poppleton ate, slept, and extracted in this launch.

worked on the tiering-up plan. The very fact that Mr. Poppleton has used it successfully these many years, and almost all alone, would show that it is not so bad after all.

The frames have closed tops. One of these stands in front leaning against the hive—see Fig. 2. Mr. Poppleton is holding another one in the other picture, Fig. 3. The top-bar has two longitudinal slots two inches long by $\frac{3}{8}$ wide. In ordinary practice these are kept closed by strips of wood running transversely over these holes clear across the whole top of the hive. It will be seen, then, that the bees cannot get to the top of the frames, and, of course, they cannot glue the top-bars into the rabbets. All the warm air is kept below. The cover can be removed at any time without a bee coming out. A screwdriver or knife-blade, as soon as the cover is removed, will spread the frames for the purpose of examination or for extraction. Very little bee-glue holds them together, from the fact that the gluing operations are confined wholly to the *under* side.

Now as to the awkwardness and bigness of the hive. Mr. Poppleton explained that, in order to make bees pay in Florida, the colonies must be *very populous*. As a matter of fact, this same principle in apiculture applies almost everywhere. No crop of honey can be secured unless we have powerful colonies powerful enough to send out a good field force when the honey-flow comes on. An ordinary ten-frame Lang-

stroth hive alone will not hold such a colony. In order to give sufficient room, the hive must be tiered up, one, two, three, or four stories high.

Right here Mr. Poppleton claims a big advantage over those who tier up. Instead of giving eight or ten frames all in a bunch he adds one, two, or three as the colony can stand. His expansion of the brood-nest is gradual, while the expansion on the vertical system is "steady by jumps."

Well, then, we will suppose that he has built his colony up to 24 frames capacity, and is just ready to move his bees to where the pasture is good. It has been argued that the ten-frame hive is big enough to handle—too big, indeed, to lift with comfort. Talk about hives three times as large, toting them down to the boat, and then toting them out again on the land! it looks ridiculous. But it is not as bad as it seems. If one has to handle a big bulky weight it is much easier to have that weight in a horizontal oblong form like a trunk than to have that same form or shape standing on end. If we were to handle a trunk standing on end the handles would be placed midway up and down of what is ordinarily top and bottom. But, no; an ordinary trunk is made a good deal after the shape of the Long Idea hive, with handles in the end. Said Mr. Poppleton, "An ordinary single ten-frame hive is unwieldy for one man to handle alone; but I can handle with a helper, whom I can hire for the occasion, an oblong box two and a half times the weight easier

The Long Idea hive as used by Victor Vargas Gamallo, Professor of Beekeeping at Havana, Cuba.

than one man can handle a single ten-frame hive;" and I do not know but he is right. If any one could hear Mr. Poppleton explain how he moves his big hives on to the boat, he would see the trick is not as difficult as it might seem.

On the other hand, Mr. Poppleton explains that he is an old man, past 70, when he cannot lift heavy hive bodies or supers full of heavy combs; but he can manipulate his Long Idea hives without lifting any thing heavier than a single comb or cover. He can get at any part of the brood-nest at any time anywhere, and almost instantly. He has no hive-supers nor hive-bodies full of frames to lift. When it comes time to move the bees, he hires a man one day to get hold of the other end of the hives.

There is never any wind powerful enough to blow these hives over. "They will stay right where put," said Mr. Poppleton; and then he explained further that he could not work a ten-frame Langstroth hive on his system. He insisted that he must have strong colonies—nothing less than 24 frames capacity. How, he asked, could he load three eight-frame Langstroth hives tiered up on his boat, and then unload again, without danger of their tipping over? There is no getting around it. A two or three story hive is not a desirable proposition for his system and location. But the same capacity all in one story can be moved.

I said to Mr. Poppleton, "The vertical system permits indefinite expansion; that is, an eight or ten frame hive, Langstroth dimensions, could be tiered up three or four

stories high, or higher if need be." He admitted this, but explained that, with his system of management, he could keep his colonies down to 24 frames capacity.

I suggested that, on the tiering-up principle, we could shut our queens down to the brood-nest with the perforated zinc, and all combs above would be clear of brood for extracting. He explained that he could do the same thing with the division-board excluders, but said that he had never found it necessary to use any thing of that sort.

When it comes to extracting he extracts from one side or end of the hive, and in a few days later from the other end. In this way he takes only ripened honey that has been all capped over. While the bees are filling one end that has been extracted they are ripening and capping at the other end. When that is accomplished it is extracted, and so on the process is repeated.

I suggested that the queen would have brood in many of the frames from which he extracts. He admitted this, but said he was careful in handling such combs. When the queen has an unlimited range, the colony is not likely to swarm if the combs are kept extracted close enough.

In the busy season Mr. Poppleton runs back and forth with his boat to the different yards. In this way he carries his extracting-outfit. In fact, he said that in the height of the season he sometimes eats and sleeps on the boat—see Fig. 4.

Mr. Poppleton has also used his migratory beekeeping in the matter of securing in-

crease. If one yard is earning nothing and doing nothing he moves it to another place where there is something doing. He said that there is quite a difference in various portions of Florida within twenty or even only ten miles of each other. At Pompano, for example, the bees would breed every month in the year. This was one of his favorite breeding-places. Here he built his colonies up and then moved to other locations on the Keys, and further down where honey was coming in.

I told our friend that the Long Idea hive was being revived in certain quarters. Two or three people in Massachusetts, and our old friend J. E. Hand, have been using a sixteen-frame Long Idea hive. "These people are making a mistake," said Mr. Poppleton. "They are not going far enough. The sixteen-frame hive is too big to be handled by one man, and not large enough to be handled by two. Sixteen frames will not hold our best colonies. Mr. Hand's scheme of converting this hive into a double-walled eight-frame hive for winter," said our friend, "is very old," and he would refer us to the back volumes of the bee-journals.

I then asked him whether it would be practicable to make a twenty-four frame hive on Langstroth dimensions. If he were going to start again, rather than take Langstroth frames he would adopt a Jumbo just two inches deeper, and make a hive to hold twenty-five such frames.

In the matter of breeding, Mr. Poppleton says there is no particular advantage in the horizontal Long Idea hive over the vertical

system except in the matter of convenience to the operator or owner. For old people, women, or any other who lack sufficient strength to lift upper stories, the single-brood-chamber principle seems to have some advantage. If it were not for the fact that it is more expensive, and that it is not adapted to the production of comb honey, it might, perhaps, receive more favorable consideration than it does. If one were to start with a hundred of these big hives to accommodate a hundred colonies he might be scared out of the business before beginning. These big hives would cost considerably more than the same capacity on the vertical principle. The tiering-up hive permits the use of narrow and short pieces of lumber in a way that would not be feasible with the Poppleton hive. Large boards of clear or sound-knot stock are expensive as compared with small pieces that have been cut out of cheap lumber, cutting around the knots.

Mr. Poppleton has carried as many as 80 Long Idea hives at a single time in his boat shown in Fig. 4, taking along in addition extracting-outfits, bedding, etc. But that was when he towed the boat with another one. When he put in an engine he could carry fifty at a time with the necessary extracting-outfits and bedding. While he sometimes extracted inside of the boat it was his practice to have a small building at each yard. This structure is of cheap lumber, and of sufficient size to answer as a workshop, extracting-building, and for storage purposes also.

To be continued

THE ORIGIN OF THE HONEYBEE

BY N. N. ALLING

One often reads that the honeybee was made to fertilize the flowers or simply to furnish man with honey and wax. People could not think that it is living for its own sake like any thing else, and had adapted itself from remote ages to the work it is now performing, and thereby secured itself an existence. Plants at the same time have adapted themselves to attract the bee by shaping their flowers and secreting sweet juices so the bee would carry pollen from one blossom to another.

People in general think the way the world is now is as it always has been, but this is not so. In the coal period there was not a single flower on any plant, although there were plenty of insects related to bees. It is natural to think that the bees' ancestors

in the coal period lived more like ants, eating what honey-dew they could find on plants and trees. The bee had no use for pollen-baskets, honey-sac, or wax-pocket. It might not have lived in colonies, as the temperature was high in those days, and there was no need for a winter cluster.

While the workers are undeveloped females now, they might all have been fully developed then. Perhaps the sting was an ovipositor, and the mothers placed the eggs in any crack or hole to hatch by natural heat, leaving the larvæ to take care of themselves as do caterpillars now.

Only slowly, very slowly, did the plants take other shapes through the next formations or periods while the bees kept pace with the plants for their mutual benefit.

The bees' antlike brothers were prevented through circumstances from developing in the same direction, but went in another, just as it often happens that human brothers, brought up in the same home, but scattered all over the world, adapt themselves to surroundings and possibilities and reach different social levels. We can always be sure that what we call a family of plants or animals is from the same ancient form, and that, again, from some still more ancient source where so many families originated before the Carbonaceous epoch.

These truths are not generally known. But the facts of geologic history will become more and more realized in spite of nursery tales from the childhood of mankind in which every thing is imagined for the benefit of man. A Swedish philosopher, Swedenborg, who flourished 150 years ago, said that bees were made to give us honey and wax; and was not wax necessary for candles? He did not dream of kerosene, gas, or electricity.

WASHINGTONIANS DISCUSS PROTECTION

BY J. B. RAMAGE

"The Relationship Existing between the Beekeeper and the Fruit-grower" was the subject of a paper read by Dr. A. H. Henry, of North Yakima, at the recent convention of the Washington State Beekeepers' Association. While all of the addresses were of a high order this one was especially so, bringing out a phase of the related sciences which is only lately coming to be fully appreciated. He was listed to address the convention a year ago, but had a severe illness at the time the association met.

The addresses, papers, and talks dealt with the range of subjects usually handled in these conventions; but especial attention was given to methods of creating good will through exhibits and of realizing upon it in sales.

The members also discussed somewhat the idea of forming a beekeepers' protective

association. There are altogether too many losing bees and honey through petty thievery. I believe we can get such an association started through a little push on the part of the members. I believe that to post notices at outyards offering a reward of \$25 or \$50 for information leading to the arrest and conviction of thieves will have a very salutary effect.

The association framed a foul-brood law which the members hope to see passed at the next session of the legislature.

The convention, the twenty-first to be held by the association, was called Jan. 6, 7, 1915, at North Yakima. The following officers were elected for the ensuing year:

President, J. B. Ramage, North Yakima; vice-president, C. W. Higgins, Wapato; treasurer, Gus Sipp, East Selah, North Yakima; secretary, S. King Cloder, Mabton.

NEW JERSEY ASSOCIATION ASKS FURTHER RESEARCH

BY C. D. CHENEY

Increased appropriations by the New Jersey legislature for investigation in bee diseases will be asked by the New Jersey Beekeepers' Association. At the convention held at New Brunswick Jan. 13, 14, action was taken to place before the legislators the need for funds in order that the State Department of Agriculture may carry on further researches into the causes of the various diseases, the conditions affecting their spread, and the methods of combating them.

The matter of holding additional summer meetings in different parts of the state was discussed. While only one summer meeting has been held annually in past years, it was suggested that four be held in the summer of 1915; but it was finally decided that two

be called, if it is possible to make satisfactory arrangements. These meetings will be educational in character, and one at least will be held in a box-hive apiary where some practical demonstrations can be made.

W. W. Case, of Frenchtown, read a very interesting and amusing paper entitled "Reminiscences." The audience was so well pleased with this production that Mr. Case was requested by resolution to send it to one of the bee-magazines for publication.

All 1914 officers were re-elected—C. H. Root, of Redbank, president; and E. G. Carr, of New Egypt, secretary-treasurer. W. Garabrant, of Ralston, was elected representative to the annual meeting of the State Board of Agriculture, and W. W.

Case, of Frenchtown, alternate. Dr. E. F. Phillips, of Washington, D. C., an honorary member of the New Jersey association, was authorized to represent the organization at the convention of the National association in Denver.

Owing to a heavy rain and wind storm during the thirty-six hours before the opening day of the convention, the meeting was not so well attended as previous meetings have been.

Hoboken, N. J.

CANDY FOR WINTER FEEDING

Some Experiments in our Machine-shop Cellar

BY GEORGE H. REA

Readers of GLEANINGS will remember that about a year ago we made elaborate experiments with hard candy for feeding. (See GLEANINGS for January 1, 1914.) It was found that candy made simply of sugar and water would granulate too much. The bees would eat away the softer portions and waste the hard crystals, which would be found in considerable quantities on the bottom-board. This trouble was overcome by making the candy with about one pint of honey to twenty-five pounds of sugar. We are again testing this out in our machine-shop cellar.

On January 9 ten small colonies, of an average strength of about four frames of bees and honey, were taken for the experiment. Over the clusters, right on top of

the hard granules are thrown to the bottom-board and wasted.

On January 26 two other lots of candy were made—one with one pound of honey to twenty-five pounds of sugar, or 4 per cent honey, and the other with half a pound of honey to twenty-five pounds of sugar, or 2 per cent honey. The bees seem to be consuming both of these about equally, except that there appear to be some hard portions in the latter which the bees seem to be eating around, and may later discard.

A point to be taken into consideration is that our machine-shop cellar is extremely dry, and it is possible that in a moist cellar the harder candy might become sufficiently soft so that all parts of it could be consumed by the bees.

Two cakes of candy were placed over the same colony. One of them (the one at the left, above) contained 10 per cent honey. The other was merely boiled-down sugar or syrup. As can be expected, the candy containing the honey was taken readily by the bees while the other, up to the time the picture was taken, had not been touched. It is interesting to note the small piece of comb which the bees built on the edge of one of the plates as a result of the stimulation.

the frames, we placed two cakes of candy molded in paper pie-plates. One cake was hard candy made simply of sugar and water, while the other contained about 10 per cent honey.

As we expected, that containing the honey was rapidly consumed, while the hard candy remained untouched for several days. The percentage of honey was found to be too high, and the honey became too soft after a few days in the hive. To-day, February 3, it is just about all consumed, while that made of sugar and water is barely touched. Where the bees are working on the latter

There is no drip whatever from the candy containing 4 per cent honey, and for a dry cellar this is undoubtedly the right proportion. We do not believe it would become too soft, even in a damp cellar.

Another interesting fact is that the colonies fed with this candy are rearing brood quite freely. Observation yesterday showed brood in all stages, and the queen laying as though it were summer time. The results of this will be reported later.

In one of the colonies the brood-nest was split through the center by spreading the combs, leaving a space about two inches

wide in which the bees clustered, hanging in festoons upon the cakes of candy placed over the opening. The first examination was made on the third day after the candy was given them. A good start was found to be made on the honey candy, while that containing no honey was untouched. To our astonishment a piece of comb was found built attached to the edge of the pie-plate containing the hard candy. This comb is shown in the engraving. Now, why did the

bees build that comb, and where did they get the material? It does not seem probable that they would consume honey from the combs for that purpose. If that is true we must conclude that they consumed more candy than they needed for food, and converted it into wax to build combs to fill in the vacant space.

These experiments will be continued, and the readers given the benefit of the observations.

BROOD-REARING SUCCESSFUL WITH ALBUMENIZED CANDY

BY T. RAYMENT

Several correspondents view with skepticism the editor's thesis of bees breeding during cellar confinement. The basis of this unbelief is rather difficult to define. If the conditions existing in the repository were favorable for the inauguration of brood-rearing, then the absence of young (not the presence thereof) should be the occasion of any wonderment.

In this far antipodean land the wintering of bees presents special problems. It is generally true that no locations in Australia call for cellar protection; but it is undoubtedly correct that the majority of our apiarists would be well advised to give the question more earnest thought. This vast commonwealth—which at times runs the whole gamut of climatic changes—experiences meteorological conditions not quite unlike those of portions of the United States.

As many are aware, the quality of the food exercises the predominating influence on insect life during the rigors of the winter. The accumulated store of vital energy is a strong factor governing the ultimate success of the insect cycle. All life is one continuous search after that most valuable element, nitrogen; and this is especially true of the *Apidae*. When the food supply contains the maximum of nitrogenous albumen or proteid (*i. e.*, the true value of the life-sustaining portion of all food), there is, therefore, a surplus available for conversion

into eggs and larvæ. This last year during our spring overhaul (August 5, 1914), we were careful to observe the condition of certain groups of colonies that last autumn were specially fed up for winter. All the colonies are housed in single-story dovetailed hives, eight-frame size, with solid bottom-boards and covers of one-inch cleated boards protected with galvanized metal. Each hive contained a one-year-old Italian queen (all these were the progeny of the

Candy placed above the brood-frames in a space provided by the addition of a 1½ inch rim.

same mother), and about four pounds of bees. Something like sixty were wintered on natural stores gathered from Victorian* spotted gum (*Eucalyptus Goniocalyx*). A few colonies contained slabs of candy made by simply pouring boiling syrup on dry beet sugar, stirring slightly, and allowing it to set in paper molds. These were then

* One of the vast family of eucalyptus indigenous to Australia.

inverted over the frames and covered with four thicknesses of newspaper, with a final fold of sacking (see illustration). A wooden rim $1\frac{1}{2}$ inches by the dimensions of the hive permitted the use of the covers described above.

Others, again, were similarly packed; but the candy was of different composition. In this case the beet sugar was boiled for one hour and twenty minutes, and some honey

During the winter the bees consumed the candy and built small pieces of new comb. In fact, the cluster passed the winter surrounded by candy stores.

was then added. When the syrup was almost cold it was rapidly beaten into a fine creamy consistency and allowed to cake in shallow paper dishes. These were then given to the bees as mentioned above.

We again varied the treatment with another group. A number of new Hoffman frames (wired as for foundation) were laid out on greased paper, and a mixture of sugar and the white of an egg was then poured in and permitted to harden. (This candy was compounded of warm beet sugar whisked up with the white of an egg (albumen) into a creamy batter, and was very similar in appearance to the icing of a cake.) These Hoffman frames of candy were placed in the brood-nests without packing of any kind.

Here are the results of our observations in epitomized form:

Group 1.—Colonies wintered on honey consumed about 9 lbs. of food, and contained a small patch of eggs.

Group 2.—Colonies on plain sugar cage consumed 5 lbs. of food, and most had a small lot of eggs.

Group 3.—Colonies on sugar and honey consumed 4 lbs. of food, and possessed eggs and brood.

Group 4.—Colonies on sugar and egg consumed $3\frac{1}{2}$ lbs. of food, and built new comb into the space so made. This new comb contained eggs and brood, a photograph of which accompanies this article.

To test the egg diet in another direction we gave some of the egg candy to colonies in group 3 with

the result that brood-raising progressed marvelously. Up to time of writing there is no new comb in any other hives. Except that the continental war has dislocated food stuffs we should certainly have prescribed an egg diet for the whole apiary.

We omitted mentioning that on odd days all the colonies gathered a little honey from the cider gum (*Eucalyptus Gunnii*). Although we have tried both cane and beet sugar we have discovered nothing. The bees apparently do as well on ore as on the other. I have in mind the British objections to beet sugar. In England the beet sugar was of German manufacture. In Australia it is made under the supervision of a Californian (Dyer). Would this make any difference?

Briargolong, Victoria, Australia.

COLORADO PRODUCERS DISCUSS COSTS, GRADING, AND EFFICIENCY

BY WESLEY FOSTER

The annual meeting of The Colorado Honey-producers' Association was held at the Auditorium Hotel, Denver, Dec. 28, 29, 1914. Some of those placed on the program could not be present, but their subjects were handled by others, and by participants in the general discussion.

The experience of a number of beekeepers in buying queens was given, and on the whole it seemed to be highly unsatisfactory;

but several admitted that they thought it should not be given up, because, once in a while, a very valuable queen is secured.

The question of the cost of producing comb and extracted honey aroused active discussion, and pencils were used by many in figuring the estimates of the different speakers. One phase of the cost concerned the depreciation that should be figured on an automobile the first year. The figures

1. Front of The Colorado Honey-producers' Association store. 2. Four of the six who keep things going.
 3. Main aisle of first floor wareroom. 4. A glimpse in the office. Mr. Rauehfuss, Mar. 5. Third floor
 (partial view) showing tinware, etc. 6. Liquefying-plant. Capacity 24 cans each 12 hours.

given by A. J. McCarty and A. C. Van Galder differed somewhat, and a short debate ensued, participated in by several others. Mr. Van Galder figured his time by the day and Mr. McCarty by the year. Mr. Van Galder has a farm that takes his time when not working with the bees, so that he does not need to figure a year's wages as does Mr. McCarty, who lives in town and is a beekeeping specialist.

Mr. Van Galder did not figure a 50 per cent depreciation upon his automobile the first year, as Mr. McCarty claimed he should. It appeared from the run of the discussion that Mr. McCarty endeavored to prove beekeeping unprofitable, while Mr. Van Galder tried to prove the opposite. As they had their own apiaries to judge by, and are both quite extensive honey-producers, I do not think a decision could be reached. Mr. McCarty claimed that, if a ten-year average were taken, his bees owed him something. Mr. Van Galder claimed a fair profit and fair wages for his time on a nineteen-year average. The bees paid him as well as or better than his farm. Here is an argument for diversified farming against specialized beekeeping. The farmer should include bees in his operations, not from a honey-for-the-table motive, but as a money crop.

The list of successful beekeepers who own and operate farms at a profit, or who are farmers and keep bees at a profit, is not small in the West.

Mr. Porter's paper, "Efficiency in the Apiary," brought out a number of points. If one has an auto he does not need a wheelbarrow in the outyard. Too many beekeep-

ers can think of only one thing at a time. If they are clipping queens they must finish that before they care for a foul colony or a queenless one, or feed one short of stores. The beekeeper should, soon after beginning work in an apiary, say after examining five hives, so size up the yard that all needful work can be attended to that day.

The grading-rules were discussed, and some changes were proposed. It was decided, however, to leave the definite changes till after the National convention in Denver, as it was thought fruitful ideas might be brought out at this meeting. It was recommended that the names of the grades of comb honey be changed from No. 1, Choice, and No. 2 to Fancy, No. 1, and No. 2 respectively, to correspond with the names of the National grades.

The Colorado Teachers' Association held its convention at the same time as the Colorado Honey-producers' Association, and Prof. Dunn of Fort Collins, Prof. Beardsley of Greeley, and Prof. Spangler of Longmont were present at part or all of the beekeepers' sessions. This goes to show that the long summer vacation makes it possible for schoolteachers to take up beekeeping for health, pleasure, and profit very nicely. Prof. Spangler has over twenty-five colonies, and I believe that Prof. Beardsley and Prof. Dunn count their colonies in hundreds.

The convention was a well-attended one, the day sessions having attendances of between sixty and eighty, and the evening sessions about forty.

Boulder, Colo.

SOME VALUABLE POINTERS ON MOVING BEES

BY J. L. BYER

In view of the fact that we are being treated to a fine series on moving bees it may seem superfluous to say any thing more at this time. But it is a subject that will stand a good deal of discussion, as beginners are constantly wanting to know about moving bees. I know this from the fact that I get a good many letters bearing on this question.

My experience in moving bees is not extensive, but I have moved them under almost all conditions. On my first attempt by train I moved 100 colonies with fixtures 100 miles; and the second trip, some 250 colonies were moved nearly 300 miles along with a full equipment of supers and other fixtures. Although both trips were made during the latter part of May, not a comb

was broken nor was there a quart of dead bees in both shipments together, so far as we could estimate.

For moving in the early spring in our latitude, if work is done at night all the ventilation I have found necessary has been provided by tacking wire cloth over the entrance. After bees have become populous, and brooding is going on rapidly, and weather is warmer, it is a good plan to screen the tops of hives with wire cloth. If the colonies are very strong, allow space on top for bees to leave the combs by having the wire cloth kept away from the top by means of strips of wood at least an inch thick—more is necessary in very warm weather. If local moving of bees for short distances is made at night, before clover

bloom, no water will be needed, generally speaking. After midsummer, when the weather is hot and hives very populous, abundance of room is necessary to allow bees to leave the brood, while water is an absolute necessity.

Fasten frames that are not of the self-fastening kind. Never take any chances on loose frames unless they are of the narrow variety and thoroughly propolized together. Possibly as good a way as any to fasten frames on top is to force with a hard-wood stick a thin wire nail through the end of the top-bar inside of the rabbet, leaving the nail sticking out a little so as to be easily drawn out again. It is not as slow a job to do this as one would think; and while there may be better ways, it is one of the easiest plans if the mover is in a hurry, and has but few tools at hand. More than once when thus situated I have used a wad of newspaper between each frame at the end, firmly pressing the wad down with the large blade of my jack-knife. Never has the plan given me any trouble.

Place on a wagon all hives to be moved, with frames crosswise of the vehicle. Most of the jolting on a wagon is sidewise. On a car, when moving by train, place frames lengthwise, as it is the shunting which causes trouble rather than side motion. When moving by train have a barrel of water at the door of each car. We moved the lot of two cars thus equipped and had no spills. The top of the water-barrel was left in place, and in its center a circle about 14 inches in diameter was cut out. For a good part of the journey I sat on one of these openings with only a blanket between me and the water, and yet I never got wet. That will show how effective it is to arrange for carrying water in this way. Our first carlot of bees was closed in with wire cloth on top with a two-inch space between the frames and the top of screen. They went through all right.

The second two cars were arranged on two plans. Part had shallow supers on top with cotton instead of wire, while the rest

were as in first shipment—covered with wire. All came through in good condition; but, all things considered, we much prefer the cotton, and would use it exclusively in shipping bees again. No, the bees will not gnaw through the cotton—something I was afraid they might do until assured by Mr. Alpaugh that there was not the slightest danger of this. Those with cotton over them had entrances entirely closed with strips of lath; and although the weather was warm there was absolutely no loss of bees. Any colonies getting the least bit noisy were promptly treated to a dash of water over the top of the cotton, and then all would be quiet.

On our last trip we used one double-decked car, even when cautioned against it by so good an authority as R. F. Holtermann. The only disadvantage we found in using such a car was that the loading and unloading were very difficult, as one necessarily had to be in a stooping position all the time. So far as we could see there was not the difference in temperature we had expected, and one lot came through just as well as the other. As a common car will take about 100 eight-frame colonies on the floor it is needless to say the double-decked car is a good means of saving work when moving a hundred or more colonies and fixtures. No crating nor decking is necessary, the bees going in one story and the fixtures in the other.

In preparing colonies for any method of moving be sure to close all cracks that bees can get out of, and then after starting you will find you have missed some. We always carry a roll of cotton batting on such trips; and as soon as any opening is seen that is letting out bees it is short work to shove in a bit of the cotton; and, once in place, it stays there.

Moving bees is at best a dangerous job. Sometimes just a little thing may help to avoid what might have been an accident or loss of bees.

Markham, Ont.

A GOOD WINTER CASE FOR TWENTY CENTS

BY ED SWANSON

It is just as necessary to have bees protected in the spring as in the winter. My bees were gathering pollen to-day (Nov. 11), which I don't think they could have done if they had not been packed. The nights are so cold that, had they been left without winter cases, it would have taken the bees about all day to warm up enough

to come out at the entrance. To-day the bees were out just as soon as it warmed up enough so they could fly. Strange as it may seem, every kind of vegetation has been dried up and frozen for three weeks, yet the bees have been carrying a lot of pollen, as I have seen by watching.

I am sending three photographs of my

FIG. 1.—The case allows plenty of room for packing.

winter cases. Fig. 1 shows the case tipped up, giving a view of the inside, with the hive in place. The space for packing is about four inches across on the sides and ends, and about six inches on top. Beside it stands the cover. Fig. 2 illustrates the case with cover on as it looks when packed for winter.

In Fig. 3 thirty-four colonies are packed for winter (with my spring wheelbarrow in the foreground).

I use planer shavings for packing. I generally put some leaves in first, so in case there are openings around the bottom the shavings will not leak out. Now, these boxes I buy at the grocery at 10 cts. apiece, cover and all. They are just the right size the way they are. I nail strips on the bottom for the hive to stand on; cut an entrance in front, and nail some legs on.

For the cover I make a one-inch rim (just the size of the box) and nail the cover board on. Then I make another rim two inches wide, and put it on the outside of this, which telescopes over the box. Then I overlay it all with one-ply roofing. These covers I shall use as shade-

boards in the summer, as they are large enough for that purpose.

These boxes cost me, finished, about 20 cts. each, not figuring labor.

I also send a picture of my homemade saw-table which I drive with a one-horse power gas-engine, and it seems to handle it nicely. I find this saw very handy in making covers, bottoms, and hive-stands.

Another photograph (Fig. 5) shows part of my bees in the foreground, and the barn

where I keep my saw, auto, and some of my supplies in the background. The building has a cement floor, and I find it a nice place to work.

Has any one ever had experience with a trailer? Would a Ford car be too light to use with one?

Then there is another photo that shows my boy with his new wheelbarrow, loaded with a super. The little fellow says he is going to be a beeman, which I hope will come true.

FIG. 2.—Ready for winter.

FIG. 3.—Thirty-four colonies packed.

How many of our beekeepers have cameras? I think every beekeeper should have one, as there are so many things that pictures explain better than any amount of description.

Spring Valley, Minn.

[Unless the trailer is built for the work

it has to do by some concern understanding the difficulties, the proposition is not apt to be very satisfactory. Even at best it takes considerably more power to move a given load in a trailer than in a specially constructed box, say, located back of the front seat.—Ed.]

QUARRYING FOR BEES

BY C. L. SNIDER

The geological formation in eastern Washington is such that there are many holes in the rocks, supposed to have been gas-pockets formed ages ago when the world was new. As there is no timber, there is no

other place for runaway swarms to go. In starting to locate them the beeman knows that they are either on one side of the canyon or the other, which helps wonderfully, while if it were a bee-tree it might be any old place.

I lined the last swarm from an old prune orchard to a point on the third bench of rock back on the north side of the canyon. After some very strenuous climbing I found them in a small ledge about ten feet high. They went in at a small hole about as high as my head. As it was late in the fall of 1913, and I wished to save the bees, I put off taking them out until Aug. 15, 1914.

When the time arrived to begin operations I took my

FIG. 4.—Home-made saw-table.

FIG. 5.—A large garage makes a fine workshop.

friend and neighbor, W. H. Yarwood, Jr., into my confidence; and after explaining to him that there was undoubtedly just "scads" of honey, and that the bees could not sting through more than two inches of clothing, he agreed to see me through.

We arose at an early hour; and after a drive of about eight miles we unloaded the tools, which consisted of a smoker, two bee-veils, a steel bar, a rock-hammer, and a box for the bees. After donning the armor and firing up the smoker we built a platform of loose stone at the base of the cliff.

Upon examining the cavity we could see comb and bees a short distance within, and found that the rock was seamed and could be broken away quite easily. We gave them a few puffs of smoke, just to let them know that we were there, and attacked the rock with bar and hammer vigorously for a few moments, laying bare a part of the nest. A stiff breeze was blowing directly against the face of

the cliff, and no bees were flying; neither did they rush out when we smoked them. After we reached the nest we cut out the combs and brood with a pocket-knife. The brood we fitted into frames in the box, and shook part of the bees on to the frames from the combs as we cut them out. The honey we put into a five-gallon gasoline-can as fast as we took it out.

After the comb had been removed we

FIG. 6.—His first load of honey.

found that we had but a small part of the bees, so we took a dipper and scooped out all we could reach. Then, taking the box to the top of the ledge, we awaited developments. It was not long before the bees in the hole became uneasy and began to fly up to the box. In about two hours we had fifty pounds of fine honey, and about all the bees (a large swarm), and were ready to

start on our drive home, feeling that we had had the time of our lives.

I shall feed the colony for winter and add them to my apiary. I have taken many colonies from the rocks, and the procedure outlined applies to about all cases in a general way, although I do not always get the bees, as they go too far back in the pocket.

Mohler, Wash.

THE NEW MISSOURI APICULTURAL SOCIETY

Missouri Beekeepers Incorporate and Boost Inspection Law

BY AUSTIN D. WOLFE

This will introduce the Missouri Apicultural Society, incorporated. The Beekeepers' Association held its annual meeting at St. Joseph, Mo., Dec. 7-8, 1914. Almost the first matter of business was the consideration of the report of a special committee whose recommendations were adopted. The substance of the recommendations was that the association proceed to incorporate; that officers for the Missouri Apicultural Society be elected at the proper time; and that those present sign the articles of agreement as charter members of the incorporated body, all of which was duly accomplished.

The gathering at St. Joseph was of more than usual interest. At least two manufacturers were on hand with an exhibit. Subjects of general interest, such as wintering bees, and spraying with its dangers, were discussed, with the customary differences of opinion. A. V. Small, of St. Joseph, read an unusually clear paper on shook swarming. O. S. Mullins, of Holton, Kansas, was so pronounced in his advocacy of Carniolans that he almost shook the faith of those who have it fixed in Italians. Beekeepers present who had tried Carniolans endorsed Mr. Mullins. Dr. L. Haseman, of Missouri University, Entomologist of the Department of Agriculture, spoke of the value of bees to the orchardist; and Dr. C. R. Woodson, who owns one of the big commercial orchards of northwest Missouri, spoke on spraying. At noon of the 8th, seventeen beekeepers sat down for a cosy luncheon, and had a good time together.

The members of the association jumped at once from the meeting into the preparation of an inspection law. In working up the law they had the advantage of the experiences of other states in preparing a bill. The association is now hot foot after the beekeepers of the state to secure their co-operation and their influence with a view to the passage of the bill. Its passage will

mean the preservation of thousands of colonies, and the saving of thousands of dollars to the beekeepers.

Officers of the Missouri Apicultural Society are: President, J. W. Rouse, Mexico; Vice-president, W. F. Fox, Garden City; Treasurer, J. F. Diemer, Liberty; Secretary, Austin D. Wolfe, Parkville.

Parkville, Mo.

[The proposed inspection law is very similar to corresponding provisions in the Ohio code, but deals with the matter more minutely. The Missouri association would give the inspector slightly greater room for the exercise of his own judgment, instructing him, for example, to visit diseased apiaries a second time only if he deem it necessary, while the Ohio law directs that he shall in every case make the second visit. In Ohio "three disinterested taxpayers" or the owner of the apiary must report in writing to secure inspection, while the Missouri inspector is directed to go ahead whenever disease is reported. In the former state, queen-breeding apiaries are to be inspected twice in the summer; in the latter, once. The Missouri bill stipulates the salary shall not exceed \$1300, while the Ohio law leaves this to the Board of Agriculture. Other differences are minor.—Ed.]

MR. A. D. WOLFE, NEW SECRETARY OF THE MISSOURI APICULTURAL SOCIETY.

Born in Montclair, N. J., in 1861; early in business; entered the ministry, and graduated from New York University and Union Theological Seminary; spent six years in Iowa and Nebraska; since 1896 has been in Missouri, acting variously as president of a school, librarian and registrar of Park College, and as pastor of prominent churches; got his first acquaintance with the bee when he caught a swarm in a coffee-box; fell in love with the art, and has ever since handled

the bee from both practical and scientific standpoints; reads enormously of bee-literature; keeps few colonies, but sets such a good example that his bees must work; makes his own equipment; belongs to the Missouri Apicultural Society; elected secretary in December, 1914.

His alertness, accuracy, training, education, and practical common sense make him a most valuable man for the place. His letters and records are models of conciseness, short-sentenced, and his points always easily understood.

Perhaps we ought to admire the man who tries but fails, but we don't. The man who tries and succeeds gets the applause, and such a man is Mr. Wolfe. When you meet him you recognize at once that you have met a real man—unassuming, modest, capable, and up to date. Our circuit judge, in deciding a case, said that a text-book twenty-five years old isn't of much value. The

same will apply to a man even more, because a man can be up to date if he will, but the poor old text-book can't.

Having served as secretary of the old State Association for three years, and having known Dr. Wolfe for the same length of time, I feel qualified to introduce him to the beekeepers of Missouri, and beg that each will give him all the assistance possible.

By the time this is read we shall be incorporated under the laws of Missouri—a point we have been trying to reach for three years; and the credit for its accomplishment rests with the good members of the society; and every member is a good one or he would not belong.

Now let every citizen, whether a member or not, jump in and help get our good foul-brood law through the legislature at this term, and we shall make old Missouri one of the great bee states of the Union.

Liberty, Mo.

J. F. DIEMER.

THE GENESIS OF BEEKEEPING ON THE PACIFIC COAST

BY EZRA MEEKER

One morning early in March, 1856, while at breakfast in our blockhouse at Steilacoom, Wash., a notice was handed me that four swarms of bees had been landed from the steamer just in from San Francisco, subject to my order. "Four swarms of bees?" I said in surprise. "I haven't ordered any bees." But I accompanied the young man who had given the notice; and, sure enough, there they were on the wharf singing their song I had with delight so often heard in the "States" in my boyhood days. The purser handed me a letter which, of course, I eagerly opened and read.

Dear Doc:—I send you four swarms of bees. Sell two swarms for \$125 a swarm, and keep two for yourself. BUCK.

William Buck and I had crossed the Plains together in 1852 to Bear River, where he took the road that led to California, while I bore off to the Northwest, and finally landed in Steilacoom on Puget Sound. He always would persist in calling me "Doc," because at one time I had read a little in medical books and thought of entering the profession of medicine.

The honeybee is widely distributed over

the world; but there were none on the Pacific Coast when Buck arrived in California and I in Oregon. Buck had made two trips back to the "States," and brought out two shipments by steamer from New York and across the Isthmus, and had been very successful. So far as I know his shipment was the first honeybee west of the Rocky Mountains.

I sold the two swarms for \$125 each; sent the remainder to my claim, and by the third year had twenty colonies. This was a time before white clover had spread over the timber land. There came a season of failure of honey from the wild flowers followed by an open winter, and I lost all but two colonies.

The raising of bees and the production of honey, however, since white clover has spread everywhere, has not been so pronounced a success in the Puget Sound country as in the eastern

section of the state where the alfalfa furnishes rich pasture and the colder winters keep the bees indoors until the honey supply is near at hand.

I have long since discontinued beekeeping, though I never lost my interest in the mys-

Ezra Meeker, pioneer beekeeper of the Northwest

terious little workers. To this day the active work of a colony during the day, and the contented hum (song shall I call it?) after nightfall has an attraction I cannot describe. This fascination has always remained with me from my boyhood days to the present, though I am nearly on the eighty-four-year mark. I have spent many an hour of rest-

ful companionship with the dear little fellows, and love to think of them as friends and admire their resentful bravery in defense of the treasure garnered from the storehouse of nature in the distant fields. Who does not profit by their lessons of unselfish industry for their kind?

Seattle, Wash.

THE FALLACIES IN THE "QUEEN ODOR" AND DISTRESS THEORIES

Another Explanation of the Smoke Method of Introducing

BY ELVIN M. COLE

The "thread of the truth" that the queen gives the colony its individual odor, Jay Smith, page 975, Dec. 15, is slender and easily broken. "Why will queenless bees readily unite with another colony?" Not because they have no queen odor, but because they have no queen. Bees do not live an individual life, but a colony life, and their hopes of life center in the queen.

Robber bees are not always from nearby colonies, as Mr. Smith seems to imply, but sometimes from a distant apiary. According to his theory they should have lost their queen odor and be made welcome.

If this theory were correct, the Alexander plan of placing a weak colony above a strong one could never succeed, as the bees having the odor of the queen in the upper story must pass directly through the lower colony having a different queen odor.

The "distress" theory of queen introduction, by A. C. Miller, page 977, Dec. 15, is no stronger than Mr. Smith's theory; and its author, so far as I know, has never advanced a single reason as to why "distress" will cause bees to accept a strange queen.

In the same issue of GLEANINGS Mr. Miller gives us a number of conditions under which his "distress" theory fails—namely, with "cracked, warped, leaky, unpainted hives," "hives of two or more chambers," or "if much of the hive is unoccupied."

"Unpainted" hives is doubtless a cruel shot at Dr. C. C. Miller, a young but promising beekeeper of Illinois.

All these exceptions which Mr. Miller notes may be easily supplied with a fertile queen by the smoke method when we understand the real principle on which the operation is based.

Those who hold to the idea that, in introducing by the smoke method, the colony odor is destroyed and bees and queen are scented alike, are equally hard pressed to explain many things. There ought rarely to

be a failure if the odor theory is true; and it is hardly possible that J. L. Byer failed to impart plenty of smoke to his bees and queens, or that he failed to have them in distress, or that at Dr. Miller's they failed to distress a single colony, or impart to them the odor of smoke.

None of these theories explain the fact that a yellow queen may be introduced into a colony from which a black queen has just been removed, or that a large queen may replace a small one, and under conditions where the bees may see the newly introduced queen. If one doubts that bees are able to distinguish between yellow and black let him turn to GLEANINGS, Feb. 15, 1914, and read the article "Color Sense of the Bee." So if the "transmission of odor" or the "distress" were true, when their distress is over, or the odor of smoke has passed away, they would be aware that the queen in the hive was a stranger.

When a colony is prospering, but little precaution seems to be necessary in introducing a fertile queen to a colony from which a queen has just been removed. The odor of a laying queen is usually sufficient, and I believe it to be the only odor that plays any part in queen introduction; also that it is a protection to her in any form of introduction.

But if the harvest is slack, or robbers begin to trouble, some method of introduction must be employed. One such method employed is known as the smoke method, sometimes misnamed the "Miller smoke method," and I believe most failures when this method is employed are due to following too closely A. C. Miller's instructions, as he seems to have failed to grasp what he calls the "basic principle" of the method.

If instead of closing the hive a certain length of time, as advised by Mr. Miller, you will follow G. M. Doolittle's plan and depend on your ear to guide you, and introduce the queen when you have the bees roaring loudly, you will meet with reasonable

success. Mr. Doolittle says in "Scientific Queen-rearing" that he lost less than one queen out of fifty by this method. I believe the following to be the true reason for the acceptance of the queen when the smoke method is used.

The smoke has demoralized the guard, and the queen enters safely. You have caused the entire colony to load up with honey; and when their fright has passed away they are not inclined to make trouble. The fertile queen is protected by her odor. Most vital of all, you have caused the bees to search for their queen in order to protect her, and they are aware that she is missing.

How quickly they become aware of her loss is made plain in Langstroth Revised, page 264. "When she is taken from them under circumstances that excite the whole colony we can easily see how they find it out; for, as a tender mother in time of danger is all anxiety for her helpless children, so bees, when alarmed, always seek

first to assure themselves of the safety of their queen."

When the smoke method is properly applied you have introduced her by demoralizing the guard; the bees are filled with honey; they have missed their own queen, and a fertile queen is in the hive. Now, why will she be accepted? Self-preservation! Why should they destroy this fertile queen and risk the life of the colony in raising and mating a virgin? Nature would forbid this risk at any time except under the impulse to "increase and multiply."

Editor Root touched the button when he said "Under-smoking or over-smoking may lead to failure." Take your time to do the work, puffing a little smoke along the entrance; keep every guard-bee back; gradually bring the colony up to a good loud roar; give them time to fill up with honey and miss the old queen, then turn in the new queen and nature will do the rest.

Audubon, Ia.

QUEEN ODOR AND BEE BEHAVIOR

BY S. G. CROCKER, JR.

While I agree with Jay Smith on a good many points in his article "Colony Odor of Bees Traceable to the Queen and to the Queen Only," p. 975, Dec. 15, 1914, I have seen phenomena which seem to point to something besides the queen odor as the source of colony identity. I think the actions of bees in entering what they know is a strange hive has a good deal to do with the conditions observed.

I have had a double hive with a queen in top, and another in the bottom, the body divided by a wire screen with an entrance to both bodies separate. I have taken the queen from the bottom hive and put the queen from the top hive in the bottom all at one operation, and the bees did not seem to know the difference. Now, why don't the bees note the difference in queen odor and ball the queen?

I have had one hive standing on top of

another on account of a lack of space and communication between them. I have removed the top hive to work on the lower one, and all the bees that came out of the hive when I jarred it, as well as those that came from the field, have settled on the frames of the lower hive and gone down among the bees without the least fighting.

When these bees think they are entering their own hive, and show no fear, they are not molested. I think that the behavior of the bees is nearly as important as the odor of the queen.

Roland Park, Md.

[Jay Smith gives room for additional ways bees have of detecting members of another colony in his statement, "There may be other means which enable bees to recognize bees from another colony; but I believe the queen is the main factor."—Ed.]

A MODIFICATION OF THE MARCHANT PLAN OF TRANSFERRING

BY FRED J. CARTAN

For the past four years I have been using a system of transferring from box to movable-frame hives similar to that of Mr. Marchant, May 1, p. 345, and without a single exception I have been entirely successful. It matters not what the size or shape the hives are from which I wish to transfer the

bees; for should the old hive be narrower I nail a strip to the side, making it equal to the width of my hive. If wider or longer I reduce by covering part of the opening.

I use a divisible hive, 5½ inches deep, outside dimensions 16 x 20, ten frames, usually two bodies for brood-chamber, super

and brood-chamber interchangeable. I run for extracted principally, and use queen-excluders on all hives.

Four years ago I bought 28 colonies about six miles from my apiary. They were in all kinds of hives; but the greater part were in the old Simplicity eight-frame in poor condition. I wished to transfer them to my hives, leaving them where they were, as an outyard. It was the middle of April, and a good deal of honey was coming in. I knew it was "some job" to transfer in the old way, for I would have to work alone, and the former owner had hived his swarms on empty frames, using no foundation, and the bees had built the combs across many of them. After thinking the problem over for several days while I was getting my hives hauled up, I decided to try putting my hives on top of the old ones, letting the bees work into them.

It was and still is my belief that brood-rearing will go forward much faster if the new hive is placed on top rather than below the old hive, for there it receives the heat from the bees and brood. It was my observation and belief that the bees would remove the honey from the old hive below to the new hive above after the brood-nest had been established in the new hive, and would not store any incoming honey in the old hive.

For the factory-made hives I cut a strip 1 x 2 x 20; fastened two small brackets to each, and, after giving a little smoke at the entrance, nailed one to the side of each hive flush with the top. I then pried off the old cover and set one of my hive-bodies on top, each frame filled with full sheets of medium brood foundation. Over my frames I use a super-cover, bee-space above and below; on that a tray two inches deep, burlap bottom, filled with planer shavings; and, last, a telescope cover covered with galvanized iron. I use the tray so that the top of the hive will be the warmest, causing the moisture to condense on the sides and ends, where it will run down and out of the entrance.

After arriving at the yard it took me less than half a day to fix up the 28 colonies. There was no mess, no stings, no interruption to the workers, for they were working as freely as ever when I looked at them after eating my lunch.

Two weeks later I again visited the yard and found the bees working heavily on soft maple, from which they usually gather much surplus, there being many trees, and very large ones, of this variety in my vicinity.

Upon examining a colony I found most of the foundation drawn out and filled with

honey excepting a half-moon-shaped space in the center of several of the central frames, and in some of these I found eggs. I immediately lifted off the hive-body, now acting as super; put on a 16 x 20 queen-excluder, and set the super back on. With the smoker I then drove the bees down through the excluder, lifted off the super again, and there, trying to follow the bees, was her majesty. Then I felt sure the system would work.

After replacing the super or hive-body carefully back in place, so as not to injure the queen, I proceeded to work the remainder. Distributing the excluders one to each colony, I lifted off the super without disturbing the covers; then put on the excluder and replaced the super. This took me less than an hour. When I left, each colony had a queen-excluder between the super and brood-chamber.

About a week later I again visited the bees and examined each colony. In every super, excepting five, I found brood and eggs, thereby proving I had the queen above the excluders. From these five I removed the excluders and covers; put on top a wire screen with a two-inch rim that I use for moving bees; smoked the bees, and drummed them up into the super. I then replaced the excluder, drove the bees below, and found the queens of all five, thus leaving the entire 28 queens above the excluders.

On this trip I gave each colony the second body with full sheets of foundation. Later, as the flow from vine maple came on, which is our greatest surplus-producer, I gave them a super with excluder below; and, still later, more supers as they were needed. I did not disturb the old hives until some time in June, when I swung my hives off the old ones on to their new bottom-boards and removed the old combs. I found them dry, and clear of every thing excepting a few cells of old pollen, all brood hatched, all honey removed above, and all drones gone. In the five which I had to drive I found more than an abundance of drones, which I trapped and killed.

From these colonies I secured a good crop of honey and one swarm. They were not interrupted in their work, and the transfer caused very little trouble. They were requeened the following year. Since then I have bought several colonies each year, and have transferred them in like manner with perfect success. As soon as I find eggs in the new combs I slip a queen-excluder under. Sometimes I drive the bees down at once and see the queen; at other times, if I am busy, I look for eggs a week later. The great point is, the bees are not interrupted

at all in their work. They store above until the queen is caught above the excluder; and then when the brood-nest is re-established they move the honey from below. I usually leave the old hive in place at least thirty days to be sure all honey is removed.

Last year one of the colonies I had purchased and transferred in this manner gave

me 90 pounds of surplus (extracted), and one shook swarm, both coming through the winter in fine condition. In fact, this colony did as well as the best I had. One should choose a warm pleasant day to catch the queen at work above. Any time between ten and two o'clock will probably be best. Corvallis, Oregon.

A FINE DAY IN SOUTHERN NEW BRUNSWICK

BY L. T. FLOYD

We placed our bees in the cellar Nov. 15, plentifully supplied with stores, consisting mainly of aster honey. We made an examination on Christmas day, and found that the fronts of the hives had a few spots of dysentery. On January 7 it rained all day, taking off what little snow was on the ground. The temperature rose to 50 degrees. On the morning of the 8th, at daybreak a thick fog hung over the valley, with a slight breeze blowing. The mercury stood at 29. The fog cleared about 11 o'clock, and the sun came out warm. In the cellar we found the bees noisy. There were more spots on the fronts of hives than we had seen in four years.

At 11:30 the thermometer had risen to 40, and while we took out one hive and placed it on its summer stand it seemed too cold for the bees to fly. At noon the thermometer showed a temperature of 45. A trip to the orchard showed the bees in full flight. We hustled to the cellar and carried our twenty colonies to their summer stands as fast as we could. We pulled off the covers

and let the sun shine on the frames and bees, giving each hive a light kick or two before we left it. By the time we had them all out, the thermometer registered the maximum at 48.

We had an hour and a half of this kind of sunshine, and the orchard was well "sprayed," I can tell you. The way those bees enjoyed that hour and a half repaid us well for the work of carrying them out. After they had had a good flight they cleaned the few dead bees, cappings, etc., off their bottom-boards, and by 4 o'clock we had them all back in the cellar again. Since that time they have been as quiet as I ever saw them.

This divides the winter pretty well for us, as we generally get them out by April 1. We think these bees would have been in very bad condition before that time if they had not had this flight. We had no trouble other winters; but in previous years they generally had a good part of their stores in clover honey. Clover failed us in 1914.

Woodstock, N. B.

OKLAHOMA BEE-LAW

BY N. FRED GARDNER

At the time of writing this article there has been introduced in the Oklahoma legislature a bill drawn along the lines advised by the Bureau of Entomology, U. S. Department of Agriculture, providing for the inspection of bees and the necessary regulations to compel the treatment and destruction of all diseases.

This bill places the authority in our State Department of Entomology, and does not create any new offices or departments, therefore the expense would be very small and only such as would be required in actually doing the work.

There has already been some trouble with foul brood in several parts of the state, and the need of the police power in this bill has already been felt. Space will not permit the printing of the bill here; but there are sure-

ly many readers of this journal in Oklahoma who keep bees and understand the importance of such a law. They surely know of the expense in many of the other states in fighting the disease after it had gained a foothold.

This is the strong argument in getting a law at once, so bee disease may be controlled cheaply before it causes a serious loss in Oklahoma. If this work is begun in time we may be able to keep the state practically free from disease.

It is not known just when this bill will come up for a vote; but if you are interested, write your state senator and representative at Oklahoma City at once, urging them to support House Bill No. 294 by Lemon.

Geary, Okla.

Heads of Grain from Different Fields

The Backlot Buzzer

The kind-hearted lady whose gardener borrowed a hive to save a swarm of bees that lit on her rose garden last summer came over here all excited this morning. She found a dead bee on the running-board.

Is It Disastrous to Disturb Bees in Winter?

Some time ago I noticed that one beekeeper said he had lost all his bees by disturbing them in the winter; but I am of the opinion that, unless he was very careless, the loss of the bees was due to some other cause. Several times I have had occasion to disturb bees in winter, but so far have never had any bad result follow it. Of course I took care to go at it with as much care as possible.

One winter I wished to transfer about a dozen colonies from box hives to frame hives, and I succeeded in doing so without any loss. I wished to get them in shape before brood-rearing commenced, as I do not like the idea of transferring when there is much brood in the hives. I waited till the temperature rose to 45 or 50 degrees. Then I moved the hives to one side, and set the new hive in its place. Then I pried the old hive apart and took the straightest combs, tied them in frames, and when I got three or four frames fixed and placed in the new hives, I shook all the bees out of the old hives, and filled out the remaining frames. The bees would cluster again before night; and even if it grew colder there was no bad result.

As a rule it is not safe to handle bees when it is too cold for them to fly; but I have done so without losing more than a few which flew out and got chilled. A few times I have had either to feed in cold weather or lose some bees; and when the weather did not happen to warm up soon enough I would open the hive and remove some of the frames till I got to the

cluster. Then if possible I would put in a frame of honey or take one of the empty combs and pour in as much syrup as I could. I would place it next to the bees and close the hive as soon as possible. I even introduced a queen to a queenless colony in the middle of winter, and it worked all right.

Stonecoal, W. Va., Jan. 18. W. C. MOLLETT.

Death of Prominent Massachusetts Beekeeper

In the Jan. 1st issue one more name should have been added to the list of prominent beekeepers who passed away during 1914. Franklin James, of New Bedford, Mass., met an untimely death Sept. 28, at 45 years of age. He was a carpenter and builder by trade. While working upon the roof of his own house, by some misstep or loss of balance he fell 35 feet to the ground, striking on his head and breaking one rib which punctured his lung. He lived 39 hours, and died without regaining consciousness.

Mr. James left a wife and three children—a daughter about 17 years of age, and two younger sons. He was an enthusiastic beekeeper, and a member of the Worcester Co. Beekeepers' Association. At the time of his death he had about 75 colonies of bees, most of which he kept in an outyard at Middleboro. A few colonies he kept at his city residence in New Bedford. He had planned to make increase to about 100 colonies.

Only two weeks before his death he had a large and fine exhibition of honey and wax at the Southern New England fair held at Lincoln Park. He often came to my home—the last time about a week before his sad and untimely death.

North Westport, Mass., Jan. 14. J. M. LEWIS.

Natural vs. Artificial Passageways

Upon the question of cutting horizontal openings through the tops of frames I quite agree with the editor, page 1000, Dec. 15. Now, the first thing I have to say against this method is, I should think the bees in the fall would fill up these crevices with propolis to such an extent that it would be practically impossible for bees to pass through them.

Those using the super covers, such as are sold regularly with the Porter bee-escapes, know that there is a half-inch space between the frames and board. These covers can be furnished by dealers with no space cut out for the escape at no additional cost. Those who wish to try Mr. Borden's method can do so in this way without mutilating their frames, and I would advise them to do so before cutting holes in the top-bars. Another advantage of using these boards is that a half-inch space is left, as I said before, between the tops of the frames and the board; and this space, being clear, cannot be filled with propolis.

Why not be content to let the bees cut their own passageways through the comb, as they will do in spite of fate? You can rest assured that by this method they will cut no more than they want.

LEWIS L. WINSHIP.

Enthusiastic Praise for Biennial Yellow Sweet Clover

Referring to the article by F. W. Van de Mark, page 937, Dec. 1, I should like to say that I got first prizes on biennial yellow sweet clover, butter, and honey at the fairs hereabouts, and against all odds, and will receive a diploma for yellow-sweet-clover hay. I have cultivated yellow sweet clover 33 years now.

Bees will not touch any thing else when my clover is in bloom. German and Austrian experts have

visited me, who claimed that it would have been incredible to them if they had not heard the noise and smelled the honey in my meadow when it is in full bloom. I have about 100 acres in yellow biennial sweet clover.

When I began to experiment with it every one said my farm had gone to the dogs. It frightened me somewhat, as it was so dazzlingly yellow, and all volunteer. If it had been white sweet clover, which grows eleven or twelve feet high, I should have been ruined. But mine grows about three feet high, and it is not as hard as wheat straw when ripe. Every thing eats it.

I am not a beekeeper, but furnish others much honey. One German claims a medium colony made 45 lbs. of sweet-clover honey in two weeks six miles from my meadow. I say rely on biennial yellow sweet clover. It is the best we have ever heard of or seen.

JOHN FREDRICK.

Defense of the Ames Bottom-board

In Heads of Grain, Jan. 15, 1915, "Subscriber" says the Ames bottom-board for four hives is faulty because, when the colonies are strong, the weather very hot, and a sudden check occurs in the honey-flow, the bees will "scrap" with their next-door neighbors.

Now, is it not the custom of most beekeepers to set their hives in pairs? While my bees are set four in a cluster they are really in pairs, for two face east and two west. Will they scrap more on these bottoms than on single bottoms set in pairs? Certainly not. I have had bees on these bottoms for several years, and never had any scraps from such a cause.

As for young queens returning to the wrong hive, that is possible under any arrangement one may use. But how often will they mistake right and left? So far as I know they never do.

As for removing cleats and placing them at the edge for summer and back to the center for winter, such work is useless, and useless work is what I am trying to get rid of.

It would be far better to use a single bottom-board for each hive on top of a plain platform, which would be the bottom of the case.

Peninsula, O.

A. C. AMES.

Wheat Shorts and Candy in Place of Pollen

I have been using common wheat shorts as a substitute for pollen, and I think it is the best I have ever heard of. I have given every suggestion a trial.

My candy is made along the lines of the Good process. I use honey and granulated sugar until the mass is thick enough to knead like soft dough. Finally I work in the shorts, leaving some on the outside of the candy to prevent sticking the bees and the frames.

I lay between half a pound and a pound on top of the brood-frames. The bees will utilize all, none will be stuck up with it, and no candy will be left on top of the frames.

This quantity of feed is enough for an ordinary colony for two weeks. More should be used as needed.

Pear Blight Not Traceable to Bees?

As to bees and pear-blight, page 974, Dec. 15, 1914, I would not maintain very stoutly that bees are responsible for blight-infection getting into the pear-blossoms, for I am not convinced that they are. However, that the infection does get into the blossoms is undeniable. Possibly the ants carry it there, and doubtless they and other insects carry it from blossom to blossom; but after it is in the blossoms,

to say that bees are not responsible for carrying it from blossom to blossom is absurd, except where there are no bees. The nectar in an infected blossom quickly becomes an active blight-virus; and no insect, bee or other, can eat from an infected flower and then from uninfected blooms without transplanting the disease. No puncturing of the flower is necessary, as the nectar itself is a highly susceptible culture medium (Burrill, University of Illinois), and the infection readily transfers itself from the nectar into the tissues of the blossom.

BENJAMIN C. AUTEN.

Finds Bee-hunting Profitable

My experience with bee-trees I believe confirms the statements of Elias Fox which he made in his article on page 32, Jan. 1. Late in August, 1913, I transferred a hybrid colony from a tree, wintered them in a cellar with my other bees, and last summer secured two colonies increase, not to speak of 75 lbs. of extracted honey from the parent colony.

Last October I captured a fine colony of three-banded Italians. A few of them showed four bands. Now while I have them nicely tucked away in my cellar I am looking forward to better returns from the Italians than I secured from the hybrids, if weather conditions prove as favorable.

Beginners and those who are not thoroughly schooled in the art of handling bees would be likely to have this performance end in utter failure.

Ehoy, Wis.

CHARLES SHELDON.

Successful Wintering on Aster Honey

Hurrah! the bees got a good fly yesterday, the first since early November. They show no dysentery, and have nothing but aster honey. They seem to be in fine condition.

Last year my bees wintered on aster honey and came through in fine shape, though they were not confined more than three weeks at a time, as compared with the recent nine weeks' confinement.

I had the finest aster honey this year I ever had. It beat clover, both in color and in flavor.

Underwood, Ind.

RALEIGH THOMPSON.

Comb Honey Fumigated with Moth-balls

Last year we sold some comb honey to a number of different stores; and after they had disposed of this consignment to their customers they received complaints that the honey had a bad taste and smell. We investigated and found that the honey was some that we had bought to meet the demands of our trade. It had a peculiar taste and smell, similar to tar and moth-balls.

A Warm Day in Winter

BY GRACE ALLEN

This must be Spring's own day of days,
The earth looks up in mild amaze;
The sun is warm—a soft wind blows
From out the mystic Land of Rose
Where days to come in spring lie bound.
This day our gallant Winter found,
And loosed her bands and set her free,
And frolics with her merrily.

And here within her magic glow
Our hives are gleaming in a row.
Out fly the bees from every hive—
"Alive!" I cry, "they're still alive!"
I kneel beside each narrow door,
And then my heart sings out no more;
For some are flying overhead,
And some are dragging out the dead.

A. I. Root

OUR HOMES

Editor

Give us this day our daily bread.—MATT. 5:11.

"THE GREAT ARMY OF UNEMPLOYED,"
CONTINUED.

There seem to be two great classes of people in this world of ours—those who work for somebody else, and the "somebody else" who employs people, or who sets people to work, and pays wages or salaries. We frequently hear it said of some one, "He is a good man to work for some one else, but he seems to have a poor faculty for working for himself." In other words, he needs a "boss" to tell him *what* to do and *how* to do it. Of course there are also many who belong to both classes, more or less. These good people "work out," when wanted, and work at home when no one seems to need them. Farmers and gardeners belong to this class largely, and we might say, also, carpenters, masons, etc., especially in the small towns and villages. This latter class also very often *hire* help occasionally. Farmers who exchange or help each other come under this class, and I am sometimes tempted to think these accommodating "neighborly" people are the very best folks in the world. As the working people greatly outnumber those who hire great numbers, it would seem naturally as if the latter would be held in great esteem as benefactors of the public at large; but it saddens one to think of the strikes, and even bitter warfare, that are almost always going on of late between capital and labor.

Another thing might be mentioned here. There are many men—yes, and boys—who work for wages until they get a little ahead, and then start business themselves, gradually employing help. Why, the largest part of our great business men started life on a farm, and also, as a rule, started as poor boys; and this fact suggests what some of you may have already guessed, that I am once more going to advise everybody to "make garden and keep chickens in the back yard"—that is, of course, in place of being idle, and belonging to the "great army of unemployed."

It has occurred to me that a little of my experience here may be helpful. I was weak and puny in childhood, as I have told you. My "pipestem" arms and legs were a standing joke in that merry family of seven*—three older and three younger. I was not only weak and frail in body, but I was slow to "catch on," believed every thing

anybody told me, etc., also bashful and timid. I mention this because my story may be helpful to other timid boys and girls. Every winter I had a recurrence of my early lung troubles, and I had such spells of coughing I used to carry in my pocket some pods of the wild lobelia to chew when the cough was bad. When the lobelia produced a slight nausea the cough let up.

I am glad to remember I always wanted to go to school; and, even if I was tormented by the big boys, the "schoolma'ams" were always my particular friends. They seemed to take the place of my good mother. I remember one time when the six children, and perhaps father too, were laughing at my credulity, queer ways, etc., that mother said, "Now, you just mark my words, and wait and see if Amos doesn't do as much in the world as any one of you." And the good faithful mother worked hard to make her prediction come true. On account of sickness and some other troubles there was a time when it was a little hard to provide for that family of nine (including the parents); and to make ends meet mother begged for a garden, and chose me for her helper. This brought me in touch with the seedsmen and seed catalogs of that early day; and very soon mother and I had the finest garden in the neighborhood. Father, although he was a fair carpenter, had a strong inclination for farming; and when I was about a dozen years old we all moved back to the farm in Medina Co. in spite of protests from the rest of the family. I wasn't a success on the farm. I was too frail and weak, and didn't seem to catch on to big fields and horses and cattle. One spring day, at dinner, mother asked if she could have Amos to make garden. Father replied, "Yes! take him and keep him as long as you like, for he doesn't 'earn his salt' out in the field." This, of course, was said as a joke; but mother quietly gave me a look that I understood. Our garden prospered as gardens made by mother and me *always* did. Perhaps father's conscience troubled him a little, for he manured and fitted our ground in fine shape, and in due time that garden and the chickens furnished fine dinners for the men who worked in the fields. Mother was waiting her chance; and one day after all had finished an excellent dinner she said:

"Father, can't you now take back a little of what you said about Amos not 'earning his salt,' etc.?"

I distinctly remember the good-natured

* In spite of my frail constitution in childhood I am at 75 strong and well; and of the seven, only one brother and one sister are left.

smile as he replied: "Yes, I take it all back, and more too; for I really believe that just now he is the most profitable man we have on the farm."

I hope the above may be a good lesson not only for fathers and mothers, but for boys and girls who are good for *some* things and not for others. You wouldn't think from the above that I was the sort of chap that would ever hire help by the dozens or hundreds, would you?*

It was not until I was grown up, had a family, and GLEANINGS was started, that I had any serious thoughts of hiring help for any other reason than to help *A. I. Root*. I have told you of meeting the young preacher, Rev. A. T. Reed. Well, he preached a boyish sermon about working for *Christ and humanity* that made my heart bound at the thought of standing by his side and working *with him* for poor needy and hungry humanity. In a prayer meeting not long after, I mentioned the matter of giving work to those in need. I have told you about one young girl whose mother told me she "wasn't a mite of use" in the home, and how this girl later on took charge of the subscription list of GLEANINGS, etc., but I did not tell you of how, in answer to my prayers, I gave work to almost the whole town—fathers and mothers and children. When our brick store that held the windmill was full of workmen, upstairs and down, we had a lot of children in the yard back of the store using boxes for seats and tables, nailing up small work, making queen-cages, etc. A friend came along one day; and after looking through the busy factory he came among the juveniles, out in the open air.

"Well, I declare," said he, "this must be what one would call 'the little end of the horn.'"

A prominent business man said a few days ago, "The first work I ever did was for *A. I. Root*, and I worked for *three cents an hour*."

I now recall that I started the school-children at 5 cents; but some smaller ones who cried because they couldn't have "a job" I set to work at 3 cents.

* When I first began waiting on Mrs. Root, a relative of hers, and a very good wise woman, remarked to Sue that she feared I would never have "vitality" enough to support a wife. That word "vitality" sort of "stuck in my crop," and I said, "Sue! we'll see about that," and I think the remark did me good. When I began to realize that I should likely be "handicapped" for life in the way of health, I began daily bathing, etc., and studied the best authorities in regard to building up a good strong constitution. This relative, years after, when she was left a widow, made our bee-veils in her own home for many years, and I fear no one has ever made them since her death with such painstaking care as she did.

Since laws have been passed prohibiting "child labor" I have often felt that they are overdoing the matter. Many children would be far better off busy at work, especially in the open air, than running the streets in idleness.

In order to give as many of the needy work as possible it became a study as to what we could make in Medina instead of sending off to buy it; and I soon had a carpenter-shop, a blacksmith-shop, a machine-shop, printing-office, tin-shop, etc., and thus I was able to employ all kinds of help, each one working at his own trade, and all this directly or indirectly for the bee business. I even went into our county jail (as you may remember) and took the boys who would much rather do *real work* than to stay there in idleness. Had I done all this to *make* money, and get rich, instead of lending a helping hand to humanity, I could not have consistently used my little prayer, "Lord, help," as I did all along.

Let us now pause a minute. A good kind friend has suggested that Edison (see p. 959, Dec. 1) could have done just as much for humanity if our Government had owned his plant; and also that, if intoxicants were sold to the people at *bare cost*, so there would be no money in the traffic, the *saloon* business would die at once. In regard to this last suggestion, if I am correct, the "dispensatory" system was right along in that line; but it soon developed there was not only intemperance but shameful fraud almost as bad as before.

In regard to Edison and others like him working for the Government, I shall have to confess I do not understand just how it could be done. Those who have written me, if I have got it right, suggest that every workman should have just what he needs and no more, and high-priced salaries are to be done away with; for *Uncle Samuel* is to own every thing, and there are to be no more either rich or poor. This condition *may* come to pass in the "kingdom of heaven," but I have little faith that it ever will here on earth. If humanity could not own and control patents, big farms, great factories, etc., I greatly fear that, without the incentive of *ownership*, little would be done.

As might be supposed in employing so many people, I was often short of funds; but I made it a Christian duty to pay off all every Saturday night; but to do this, other bills for stuff often had to wait. At one time when I was pushing ahead and branching out almost recklessly, a good friend in our Medina bank wrote me a letter. A good many old heads in business were predicting disaster ahead of me, and

this friend asked me to consider not only what such a thing would mean to my friends, but to those who were beginning to have faith in God and his promises to his children, for all knew I was praying daily for God's guidance.

I thanked "Robert" for his kind plain letter, and then added, "To show you how in earnest I am in my thanks, just watch and see how I am now going to pile up something against a 'rainy day.'"

Now let me explain that my good pastor, Rev. C. J. Ryder, had been talking with Robert about this very matter before Robert wrote me that letter; and some time later I got a letter from Dr. Ryder, with congratulations, saying Robert had written him I had \$10,000 in the bank, and all outstanding bills paid in full.

I give the above incident to show the great need—yes, almost the *necessity*—that one who employs *must* have some ready cash ahead. From that time forward I found out the great advantage of having some money ahead for emergencies.

Now a word in closing, to the unemployed. First, "get busy" at something. If no one needs you, get busy at home. Cut down expenses in every direction. Run errands; do every thing yourself. Make the things you need; improve your place; your home; stop the outgoes.

Second, cut down the expense of your "daily bread." I have made little reference to our text; but we are coming to it now. Mrs. Root wanted some graham flour. We usually grind it, as I have explained, from the wheat we brought from Ohio; but that is so near gone I bought some. They had it only in fancy pasteboard packages at 25 cts., and the packages contained only 44 oz. of flour.

May the Lord be praised for the recent law compelling a plain printed statement of the amount of food placed in either tin can or pasteboard package. Well, 25 cts. for 44 oz. will be at the rate of about 9 cts. per lb., and this package was put up when farmers were getting probably about 90 cts. for their wheat. Cost of wheat, $1\frac{1}{2}$ cts. per lb.; and graham flour, which should contain every particle of the wheat, is 9 cts. per lb. How is that for "profit"? Since then I have found some "whole-wheat flour" at 5 lbs. for 25 cts. Now, this is not all. This fancy package of graham flour, with reading in fancy letters all over it, telling of its wonderful "superiority," does not *compare*

with the flour from our little mill from the wheat we grew ourselves in Ohio. The graham flour is only one among hundreds of illustrations. If you are out of work, and the matter of "daily bread" begins to trouble you, steer clear of "fancy packages" of food. Get a little mill, or use your own coffee-mill. (You will be far better off with the wheat coffee.) Hunt up some good wheat and corn. Get it of the one who grew it if possible. Make shortest *possible* cuts from "producer to consumer" in all the food you use. As soon as spring opens, make garden and thus take your "daily bread" straight from the loving hand of "Our Father who art in heaven." The same with chickens. If you can scrape up enough to buy a laying hen you can commence this day. If you live as we do in the South, you can plant seeds every day in the year. Save the leaks; make short cuts; and when you come to ask God's blessing at the breakfast-table you can, with a clear conscience, say, "Give us this day our daily bread."

THE FLORIDA REDBUG.

I have several times mentioned the *Florida Grower* as a periodical that every one interested in that State should subscribe for, because it really *does* tell "the truth about Florida." Now read the following:

Can you tell us through your columns what to do for the "chigger," or "red-bug," that pesters us all during our stay, the one drawback to our visit in Florida? I'm not afraid of any thing else that I can't see; but this redbug works at night and keeps us awake.

Mrs. G. W. B.

Answer.—The redbug, or chigre, is certainly a pest wherever it is found, and I discovered it in Illinois and Ohio long before I came to Florida to live. There are people who haven't the slightest acquaintance with this little villain, even though they walk beside those who are in an itching agony, and the reason for this I am not able to suggest. They have always bothered me more or less, but I find that I am not poisoned by them as I was in my early introduction to them. No doubt one becomes vaccinated, as it were, with their poison, and in the course of time enters the ranks of the immune. I know of no infallible specific against their attacks, but I can give various remedies that have served me and my friends in the past, and each is more or less efficacious. As a means of protection before going out in the grass, rub the feet and ankles and well up toward the knees with a highly saturated solution of spirits of camphor. This is bitter, and they must sample this before they can puncture the skin, and often they back out rather than investigate further. Listerine will sometimes prove a protection, and so will kerosene and bacon grease. The latter two are not pleasant remedies to carry about on one's person, but neither is asassaenda, and you remember how we once stood for that odorous odor to protect ourselves from smallpox. Bacon grease and kerosene are godly things compared with that. If you find yourself in possession of the little savages the bacon grease or kerosene will give them a death blow about as summarily as anything I know. Let

* Yes, the fancy package *did* contain also a coupon, and when you got a lot of coupons you could "draw" a wonderful "prize," etc. *Gambling*, in the matter of "daily bread"! Is that the way to reduce the "high cost of living"?!

this be followed by a very hot bath. If one has the luxury of a lath-tub in the home, a vigorous scrubbing with a stiff brush in water as hot as can be borne will destroy those that have not yet buried themselves in the flesh. If the deed is done, then one can only spat the itching spots with camphor, alcohol, or ammonia, and make the best of it. You'll get over noticing them after awhile, which will console you more or less until that happy time arrives.

Before I saw the above I had been wondering if one could ever become really immune to redbugs the same as he does to stings of bees. My experience does not quite agree with it. If, however, I could keep in a beaten path and avoid brushing against weeds and palmettos back in the woods I would not have very much trouble. Sometimes something comes up when I am in a great hurry to get through the thicket, and

I take my chances. Then I am troubled by redbugs. If, however, I should rub my feet and ankles with citronella before going out in the thicket, I have little or no trouble; and as this citronella keeps off mosquitos and sandflies I would suggest it as the best and simplest preventive. Another thing, where the woods have been cleared up and crops planted, there is no trouble with the redbugs, and there is little or none to people who live in town unless they get out among the wild woods and scrub palmettos. All such pests belong more or less to new countries before the land has been settled; and, as suggested above, there *are* certain persons who are never troubled, no matter where they go.

HIGH-PRESSURE GARDENING

A SINGLE TREE WORTH \$30,000.

The article below was mailed us by our youngest daughter, with no explanation as to where it came from, except the remark, "I thought father might like to see this; perhaps it is a fake." Before deciding to give it a place in print I submitted it to my good friend Reasoner, and he replied that it is substantially true, and that one of our Bradentown people with whom I am acquainted had actually seen the tree. To make sure, I called on the lady and got her endorsement. With this introduction I give it to our readers.

The most valuable fruit-tree in the world, so far as can be learned, is an avocado, or alligator pear-tree, owned by H. A. Woodworth, who lives on a five-acre ranch at Whittier, Cal. The tree is insured against damage by wind or fire with Lloyds, of London, for \$30,000. During the year 1912 it yielded its owner a profit of \$3206. The tree is enclosed by a slat fence 38 feet high, which the insurance company requires Mr. Woodworth to maintain.

Seven years ago the tree sprang from the seed of an avocado that was growing wild in the highlands of Mexico. Burt Rideout, a Los Angeles County nurseryman, planted the tree on his five-acre ranch; and when it was three years old he sold the ranch to Mr. Woodworth, a retired Wall Street broker.

Nobody suspected that the tree would prove the money-maker that it is. The average alligator pear-tree does not come into bearing until it is eight or ten years old. Mr. Woodworth's avocado began bearing when it was only four years old. During the fifth year it produced \$1716 worth of fruit and bud wood. In its sixth year it netted its owner \$3206, of which \$1500 was derived from the sale of alligator pears, at the rate of \$6.00 per dozen, and the remainder, or \$1706, was derived from the sale of buds at from ten to twenty-two cents each.

Owing to the scarcity of productive avocado trees there is always a strong demand for bud wood with which to bud young seedlings in the nurseries; and bearing heavily there was a general rush for bud wood. Mr. Woodworth sold all the buds that he cared to take from the tree, and raised the price of

buds to twenty-two cents in order to stop the demand, but that did not check it.

"I was afraid for a while that we were going to injure the tree by cutting buds," he said; "but I guess we didn't hurt it in the least. At any rate, it is loaded with pears again. We took more than 1500 pears from it prior to New Year's day, and I should not be surprised if the total crop amounts to 3000 pears, for the branches are filled with green fruit which is hardly distinguishable, because it is nearly the same color as the foliage." Mr. Woodworth is very proud of the tree.

"That the tree bears any fruit at all is indeed surprising," he remarks, "for it hasn't had half a chance since it made a reputation for itself. Every day throughout the year the crowds of tourists who visit Whittier to see the sights come here to pay their respects to the tree, and they will never be satisfied until I take them within the enclosure so they can touch the tree, break off a twig, take off a leaf, peel off a little scale of the bark, just to see what it looks like.

"Curious persons keep the ground around the tree trampled down so hard that it would be useless for me to attempt to fertilize it. In that connection I may add that fertilization for avocados is a waste of time and money. So is sub-irrigation.

"The avocado comes from the highlands of Mexico and Central America, where it gets little or no moisture from the surface soil. It has a tap root that goes straight down to moisture. With such roots as that, it is useless to try to introduce water and fertilizer from the surface.

"Another thing about the avocado is that it does not need spraying. It is more nearly free from pests and disease than any other tree grown in the West."

The prize tree blooms in March. The crop begins maturing in September, and continues to ripen until late January. A curious thing about the alligator pear is that it is worthless if permitted to ripen upon the tree. The pears, which are light green in color, must be gathered when they have reached the proper size, and laid away in a dark place to mature, like bananas; and when they become mellow they are ready to serve.

The average avocado, when mellow, weighs from eight to ten ounces. It is neither acid nor sweet. It contains a high percentage of vegetable fat—more than that contained in any other known fruit. Persons who cannot digest other fruits find the avocado easy to assimilate. It can be served as a sauce or

dessert. Some use sugar on it, some use salt, vinegar, olive oil, pepper, or spice, and some eat it raw. It is a fruit that may be served in innumerable ways, all of which are good.

The alligator pear-tree is just now claiming the attention of orchardists in many parts of the world. It is not many years since its introduction into this country. The first trees brought into the United States came from Hawaii and South America. Nearly all of them died. The alligator pear from the Mexican highlands has proved to be the best, for the reason that it is accustomed to a high altitude in its native haunts, and it withstands the cool weather of the Southern States quite well.

Right here come in some tables of figures; but as they are not very clear to me I omit them. The paper closes as follows:

The avocado selling at 40 cts. was a two-pound one. It thus sold at 20 cts. per pound. On an average it takes eight eggs to weigh one pound. With eggs selling at 50 cts. per dozen, or 5 cts. each, they would sell for 40 cts. a pound. With avocados selling at the enormous price of \$6.00 per dozen, and possessing, as has been shown, the same food values as eggs, it will be seen that they are selling for 15 cts. a pound cheaper than eggs are selling for, when the latter move at 50 cts. per dozen. The same line of reasoning will show that the consumer could afford to pay \$7.20 per box of 48 avocados; and at the same time he can buy eggs at 15 cts. per dozen.

Thirty-eight feet high is an awful "fence," and Mr. Reasoner felt sure the fence was only about *fifteen* feet high; but Miss Wyman says she thinks 38 feet is correct. She says it is a tremendously big tree, and the fence went up nearly to the top. As the avocado does not stand much frost I have been wondering if this fence were not, at least originally, for weather protection as well as to keep out thieves.

The alligator pear has been grown more or less in South Florida for 20 years or more. Reasoner says of it in his catalog, "The most valuable fruit in the American market." Until quite recently it has been out of season when we got here in November, but now we have a variety called "Trapp" that ripens from November to January, and I am pleased to tell you that we have three trees, now growing in our garden, that cost \$2.00 each, catalog price. I have given you this story after finding it is substantially true, because it illustrates so vividly the *possibilities* of agriculture and horticulture. Of course it remains to be proven that buds from this wonderful tree will produce in other localities as the tree does in its California home; but we shall soon know about this.

As I write, this evening of Dec. 8, I realize that in a few more hours I shall be 75 years old. As Mrs. Root was about to retire we have just knelt together, and I have thanked the kind Father that he has permitted us to live thus long, with physical strength and activity almost unimpaired. I thanked him, too, for the progress I have

been permitted to see in giving hungry humanity better and more nourishing fruits and vegetables, and also the better and greater results* for those who till the soil. I can easily recall when tomatoes were unknown as an article of food, and yet *now* the growing and putting them up for a wholesome and nourishing food is a great world-wide industry. I might say almost the same thing of celery and many other things. Our Department of Agriculture is just now "ransacking the whole wide world" to see if there are not somewhere, heretofore unnoticed, things that are better than what we have already. What a glorious thing it is to have a part, just a little part, in helping to bless humanity after we are gone! If I am right, the good man who gave us the Concord grape was scarcely recognized and remembered until after his death. Once more, what a "glorious thing" it would be if all humanity and all nations were working in harmony and brotherly love to *hunt up and develop* "God's gifts" heretofore unknown and unrecognized, instead of seeking to destroy each other!

FORTY-FIVE CENTS EACH, WHOLESALE, FOR TRAPP AVOCADOES.

While giving place to the clipping below, let me say the avocado trees in our garden are of the Trapp variety. They came from Miami in wooden boxes about a foot square (like potted plants), and cost \$2.00 each.

RECORD PRICE FOR AVOCADOES.

Miami.—Forty-five cents each for avocados. This, it is believed, is absolutely the record price ever received in the wholesale market for this fruit, and was paid in Chicago for a crate of Trapp avocados raised in the Miami Beach orchard. A telegram received by T. J. Pancoast, secretary of the orchard company, yesterday afternoon contained the information that \$21.00 had been received for the crate. Investigation of the records showed that there were just forty-six avocados in that crate, which makes their price a fraction over 45 cents each.—*Fruit Trade Journal*, New York.

MAILING DASHEEN TUBERS ACROSS THE OCEAN, ETC.

Mr. Root:—Noting your trouble in sending dasheens by mail across the ocean, there is no trouble provided you dry the tubers about ten days in a dry shaded place, then pack in perfectly dry excelsior. We ship a good many *caladiums*, etc., in this way.

English walnuts have turned out failures in Florida; also are subject to root-knot. They do not like our long warm and humid summer. We are about 500 miles too far south for them, as they will grow moderately well in the upper part of the southern states.

Oneco, Fla., Jan. 11.

E. N. REASONER

We have recently had reports of tubers going even to South Australia and then germinating. We too have failed here with English walnuts.

* You have all noticed, more or less, what the "corn boys and girls" have done in developing possibilities.

TEMPERANCE

RUSSIA; ITS EMANCIPATION AS THE RESULT OF THE WAR, ETC.

We clip the following from the New Britain (Ct.) *Herald*:

DRUNKEN RUSSIA TO SOBER RUSSIA.

This terrible war raging across the seas has been a series of astonishing happenings. None, perhaps, has been more unexpected than the complete abolition of the liquor traffic in Russia. The prohibition of the sale of alcoholic drinks was a temporary war measure to prevent disorder during the mobilization of the army, which was a powerful acknowledgment that alcoholic drinks are a disturber of peace and an excitant to the worst passions of human nature.

At the end of a month the transformation from drunken Russia to a sober Russia was such an illuminating lesson in favor of absolute prohibition of the sale of intoxicating drinks that the Czar, in answer to a solicitation from the president of the Russian Union of Abstinence, that the sale of spirituous liquors be forever discontinued, replied:

"I thank you. I long ago decided to interdict for all time in Russia the sale of alcoholic drinks by the government."

George Kennan, the proficient critic of Russia, says in the *Outlook*: "For the first time in the history of mankind one-seventh part of the habitable globe has gone dry, and 170,000,000 people have stopped drinking intoxicating liquor. For many weeks the sale of vodka has been completely suspended, and the whole population has looked at the European situation through absolutely sober eyes." Our own government, which prides itself upon its advanced civilization, would do well to pause and ask itself if its boasted moral superiority can be maintained in the face of this grand step taken by the Czar of all Russia who has banished from his empire an evil that has not one redeeming quality, but is an unspeakable and unqualified menace to the peace and happiness and prosperity of every nation within whose gates it is tolerated.

The revival of industry, thrift, and self-respect which so quickly followed the suppression of the liquor in Russia was an object-lesson which the Czar of Russia was keen enough to perceive, and great enough to accept and apply to the good of his people; and herein lies his superiority over all other rulers of the world. It was the Kaiser of Germany who, not many months before the war began, said that the nation that would rule the world would be the nation that abolished the liquor traffic. This war has revealed to the world a new Russia in more ways than one, and the world may well tremble before a sober Russia. Mr. Kennan, who has long studied Russia at close range, says: "In the list of Russia's spiritual awakening, the spontaneous and universal welcoming of prohibition as a great national blessing for which everybody is ready is not the only proof of her extraordinary growth," and adds, "If the war should do nothing more than free Russia from the curse of vodka it would be worth all that it can possibly cost in treasure and life." Must our own beloved country pay such a price to become a sober nation? We may rest assured that the Kaiser's opinion was not based on an idle dream, but upon hard common sense and a knowledge of the degenerating influence of alcoholic drinks.

Do not we as a nation need as keen human efficiency as the ball-player? In *McClure's Magazine* Connie Mack's management of his ball team is good logic for the government of a people to follow, and Russia has followed it. Connie Mack says:

"Keep in mind that steady—'moderate'—drinking gets a ball-player in the end just as sure as booing alcohol slows a man down inevitably, and slowing down is the reason for the shelving of by far the majority of players." He also says, "You ask me why the world's champions have done so well. I have to answer: Because of the kind of lives they lead, and their consequent ability to think and act quickly in an emergency. It is not a matter of morals to our club, but of human efficiency." *Are we to require less efficiency in our legislators than is required in our professional sports? It is a fact that on the "hundred thousand dollar infield" not a man has ever known the taste of liquor. Why not apply the same rule to our senators and representatives? Do we not need as high an efficiency "to think and act quickly" in our law-makers as in our ball-players?*

The fact of it is, we have not brought to bear the same intelligent common sense in choosing our law-makers as the manager of the field of sports has in the choice of his players; hence the colossal failure of our democratic government. Lastly, listen to these sensible words of Connie Mack: "From the standpoint of the public—the people who pay their 25, 50, 75 cents or a dollar to see good baseball, they are entitled to see the player at his best—not slowed up by drink." Are the tax-payers of America entitled to less? The Kaiser of Germany was right. The nation that dominates the world will be the nation that is not slowing up through drink. Russia dominates the world to-day in spiritual superiority. She has recognized the right of her people to a government not crippled by alcoholic drinks.

America should have been the nation to set the world this lofty stand—and—alas! she has failed just at her most boasted point—her moral and spiritual superiority. Russia will ever stand on the pages of history as the first nation to break the shackles of the liquor traffic from off her people. The great man is he who seizes the opportunity and crystallizes it into a living fact. The Czar of Russia stands at this hour the greatest man among all nations.—*Marinda C. Butler Robinson.*

A FORETASTE OF HEAVEN.

A country vicar, writing in the *Novoye Vremya*, says of the changed conditions in Russia under prohibition:

"The old women in the villages can hardly believe their own eyes and ears, so changed are their men-folk. Not a hard word, not a row, but everywhere peace, kindness, and industry. War is said to be hell; but this is like a foretaste of heaven."—*Union Signal.*

TOY PISTOLS, ETC.

Mr. A. I. Root:—GLEANINGS came in to-day; and, as I always do, I turned first to your letter and then the article following; and to the letter from Chas. R. Hill I want to give my support. I have only one boy, 13 years old, and, of course, I think more of him and of my 78-year old father than of any other man or boy living; but I have never loved him well enough to buy for him a toy pistol. I think a father's love should run in an entirely different channel than that of pistols for his boys.

I hope you will enjoy the winter in Florida, and live many years yet to keep mankind in the straight and narrow way.

Granulated Sugar Going up Again

SHORTLY after the opening of the Great War, sugar rose to nearly 9 cents. Since that time it sagged until it finally got down to \$5.25 per 100 lbs. The latest report, however, shows that it is again taking a sharp advance. This was rather to be expected. This will increase the outlet for cheap honey.

Our Cover Picture

OUR cover for this issue shows the apiary of Wm. Beucus, Cadott, Wis. As described in his article on another page the hives are arranged along a steel track and by means of a small car or truck the supers may be pushed along to the honey-house without much effort.

Doubtless the average man will feel that a wheelbarrow or two-wheeled cart that can carry eight or ten supers at a load would be a simpler proposition, taking every thing into consideration. Nevertheless, the plan is an ingenious one, and we are sure the readers of GLEANINGS would like to have a further report of it after it has been tried another season.

Steam-knife Boiler Burst

A BEEKEEPER using a ten-pound pail as a boiler for his steam uncapping-knife was severely burned on the arm by the bursting of the pail, due to the small hole, in the end of the knife for the escape of the steam, being stopped up. So far as we know, this is the only accident of the kind, yet possibly a word of caution might not be out of place.

In ordinary use the opening in the point of the knife will not become clogged up. Sometimes, however, if the knife is used to poke away the accumulation of cappings in the uncapping-can, or melter, there is some tendency for the hole to become filled up—especially so in case of the melter, as melted propolis or wax may be forced into the opening. It is better to use a stick or wooden paddle for this kind of work.

Before using the knife, blow through the tube to make sure that the opening in the end of the knife is clear. If you have forgotten to do this, and the tube is already attached to the boiler, you can easily ascertain whether the opening is clear by placing the point of the knife in your mouth and sucking the air out of the knife. The safest way, however, is to blow through the tube before attaching it to the boiler.

Beekeeping vs. Spraying in Bloom

THE Massachusetts Board of Agriculture will shortly issue a poster indicating the proper time for spraying fruit-trees and showing that, while trees are in bloom, it is not only ineffective as a prevention against fruit-pests, but directly dangerous in some cases, being liable to spoil the blossoms and to cause the death of bees, thereby greatly reducing the amount of fruit set. It is hoped to have ready shortly thereafter, for general distribution, a more extended circular or bulletin on this subject. The poster is intended for use in public places. Both poster and circular can be obtained as soon as issued, by addressing the Honorable Secretary of the State Board of Agriculture, 136 State House, Boston, Mass.

Snow, Plenty of it, this Winter, Presages Well for the Beekeeper in the Clover Districts

THIS winter so far is proving to be one of the old-fashioned kind, with a large amount of snow. In a recent trip through the East, we found that snow had fallen all over Virginia and the northern and eastern states, and is and has been very plentiful in Ohio. Much snow during the winter is a better guarantee for a good crop of clover honey than any other one thing. Experience shows that clover is more apt to fail after an open winter with alternate heaving and freezing of the soil, with little or no snow, than under the opposite conditions. One reason why northern New York.

Michigan, northern Illinois, Wisconsin, and Minnesota will produce clover honey when those parts of the country further south will not is because they have more snow. It has been shown that Ontario, Canada, will very often produce a crop of clover honey when the season will be almost an entire failure in Ohio. The former has snow when the latter does not. Well, we are having a large amount of snow this winter, and this is one of the most hopeful signs we can have that there will be a good crop of clover honey providing a drouth does not come on in late spring or early summer. Without such a drouth a clover crop is assured.

Another thing, snow assists materially in the matter of wintering bees when placed outdoors. See what J. L. Byer says on page 97 of our last issue.

The Massachusetts Convention

FARMERS' week at the Massachusetts Agricultural College at Amherst, March 15, 16, and 17, is to be featured by the Massachusetts Beekeepers' Convention and Apiary Inspectors' conference. A program and information may be secured by addressing the Extension Service of the Massachusetts Agricultural College.

Dr. Burton N. Gates will open the convention with an address on "Honey Products for Massachusetts," and on the following day will explain the Massachusetts wax-rendering service. Rev. D. D. Gorton, of West Springfield, Mass., will talk on swarm-control measures as practiced in Michigan. Geo. B. Howe, of Black River, N. Y., who has spent years in developing a race of bees, will explain methods and results. One of the most unique addresses will doubtless be that of C. C. Dowdey, entomologist from Uganda, East Africa, who will talk on beekeeping in that little-known region. Dr. H. P. Fernald, J. L. Byard, and G. H. Cale, all of the agricultural college, will give talks respectively on the following subjects: "Orchard Spraying Practices with Relation to Beekeeping;" "A Procedure for Late Fall Queen-mating;" "Experiences in a New York State Commercial Beeyard."

On Wednesday, March 17, the second convention of apiary inspectors in eastern United States will be called. The program will be open to all interested with a session for official inspectors, and speakers will be selected from the inspectors and authorities who may be in attendance. The subjects proposed comprise the methods and duties of inspectors, ways of combating European and American foul brood, and other bee diseases, transportation problems in relation

to the spread of these infections, and resistance of race, variety, or strains of bees in European foul-brood suppression.

Doubtless the subject of spraying in relation to beekeeping will come up for consideration since it is very closely associated with apiary-inspection work, and is quite a prominent point in the minds of beekeepers in eastern Massachusetts to-day.

The National Convention at Denver

THE National Beekeepers' Association convention in Denver was a more harmonious gathering than for some years past. The delegate sessions were handled with dispatch, and a better understanding among all the naturally diverse interests was evident.

Twenty affiliated organizations were represented, and the physical fact of separation by wide expanses of country and the resulting altered conditions made absolute harmony of interests impossible. There was, however, a spirit of compromise manifested, and it was apparent that things have been given a decided turn for more harmonious action for the future.

The publishing of an official organ and the carrying on of the business features has been apparently happily adjusted, and there seemed to be a general feeling that the result will inure to the satisfaction of all concerned.

Those of the National affiliated organizations that are more vitally interested in the business features will doubtless arrange to incorporate an auxiliary corporation with a capital stock that will assume the management and control of *The Beekeepers' Review*. While this organization will be separate and distinct from the National Beekeepers' Association proper, the relation between the two, it is believed, will be friendly and voluntary.

The Review will remain the official organ of the National Beekeepers' Association as before. Each organization, however, reserves the right to discontinue the official recognition of the other. But as both will be made up of National members to a great extent the relationship seems likely to be permanent.

The business sessions were entirely separate and distinct from the other sessions for the consideration of papers and general discussions. The former were held at earlier periods; and, while they were open to the public, only delegates had a vote.

President Gates showed that he was a good presiding officer in that he didn't hesitate to use the gavel when occasion required.

At the general session a good many matters of importance were discussed. In our next issue we hope to give a very brief synopsis of the most important, and possibly a picture of the convention.

On the evening of the 17th, in the auditorium of the hotel, the Colorado Honey-producers' Association gave a banquet to the members of the National Beekeepers' Association. Dr. E. F. Phillips, of the Department of Agriculture, Washington, D. C., acted as toastmaster, and a good one he was. There were over a hundred plates set, and the music and toasts were of the very highest order. There were frequent bursts of applause and laughter. The affair was a success in every way; and on behalf of the guests Dr. Phillips suitably expressed the thanks of the National to the Colorado Honey-producers' Association for the splendid entertainment.

The following officers were elected:

President, Dr. B. N. Gates; vice-president, Frank C. Pellett; secretary and treasurer, Wesley Foster; directors, E. D. Townsend, E. J. Baxter, J. H. Stoneman, E. G. Carr, Geo. W. Williams.

Caucasians and Other Black Races Adapted to the South on Account of their Early Breeding

MR. J. J. WILDER in the Feb. 1st issue, p. 69, speaks in the highest terms of the Caucasians, and he wonders why it is that the editor has had so much trouble with their bad swarming when neither he nor his customers have had any such difficulty. It is true Mr. Benton did speak of their swarming rather to excess, and we found them to be even worse than Carniolans. Possibly we had a bad strain of them; but although our Caucasians came from different sources, they all behaved alike.

The question whether they swarm to excess or not should not be given too much consideration. The *real question* after all is, "Are they money-makers?" We quite agree with Mr. Wilder that they are excellent for building up in the spring—better than Italians perhaps. The same may be said of Carniolans. It appears at this writing that the Virginia brown bees, or what might be called the old-fashioned black bees, are ahead of Italians in this respect at our Virginia apiaries.

This matter of early building up is certainly a valuable feature; and for beekeepers in the South, and perhaps in other localities, it is a factor worth considering.

During these war times it would be very difficult to import Caucasians, for the re-

gions where they are bred, in the extreme southwestern part of Asiatic Russia, are in the midst of the heaviest fighting at the present time. We have none in stock at our yards. In fact, we were compelled to discontinue using them in this locality on account of their swarming propensity which with us was intolerable.

We are coming to believe that the black strains, be they black bees, brown bees, Caucasians, Banats, or Carniolans, will breed up better than the pure yellow strains. The fact that blacks seem to be the *persistent* and *dominant* race would indicate that they must be a strong race capable of standing severe winters. The yellow strains of bees are essentially a tropical race, while the blacks—at least many of them—come from comparatively cold climates.

An exception should be made, however, in favor of the leather-colored strains of Italians that come from the mountainous regions of Switzerland where much the same climatic conditions prevail as are found in northern Italy. So far we have found these leather-colored bees come through as well in severe winters as the black; but we shall have to admit, when all is said, that they do not breed up quite as rapidly.

=====

How the Bees are Wintering Out- doors in those Big Winter Cases

TO-DAY, Feb. 12, the weather has moderated enough so that the temperature has reached 50 degrees F. There has been no sunshine, and no bees flying out. Part of our bees outdoors were put in quadruple packing-cases of the Holtermann type, a part in the regular Root double-walled packed hives, and a few (only four) in single-walled hives containing the double telescope cover. The showing in quadruple packing-cases is excellent with this exception: In the case of a very few of the strong colonies the packing material had crowded the entrance cleats over in such a way as nearly to close the entrance but not quite. In front of these hives we found large numbers of dead bees, and the entrances practically closed with their dead carcasses. On opening up the hives we found the colonies overheated and excited for want of ventilation. Had we not arrived at just this time, to clear the entrances they probably would have died in a day or two by worrying to get out, and they may succumb before spring, as it is. The entrances were partly closed on some of the weaker colonies; but as yet they seem to be all right. We enlarged them all to full size after clearing them out.

Examination of the colonies in the individual double-walled packed hives showed that there was unquestionably a greater mortality. In fact, about 30 per cent of the colonies were dead outright. On opening up the hives we found the clusters actually starved to death, with plenty of stores within two combs' distance, either on one or both sides, because the weather remained cold so continuously.

In the quadruple packing-cases we found no such conditions. Not a single colony was dead, and on the day of our examination the bees were spread over the combs as they would be in the summer. The ten or twelve inches of packing all around is undoubtedly warmer than two or three inches of packing.

There is another condition that may not be all in favor of these big quadruple cases: The bees were so warmly packed that the clusters apparently never really formed except in extreme zero weather. The danger is that this condition will lead to brood-rearing prematurely, sap the vitality of the bees, and possibly weaken or kill them by spring. The question is, then, "Is it possible to overdo this matter of packing?" There is a certain advantage in having a colony during winter in a nice compact cluster. In that condition there is less activity, less consumption of stores, and no brood-rearing. Such a colony, we know, will winter well. Now, then, will the colony that never clusters all winter, or seldom does so, do as well as one that is in a compact ball practically all winter? The sequel will show this spring.

We have examined the colonies in single-walled hives at our home yard. They were powerful colonies early in the fall, and are showing up nicely now. Indeed, their cluster formations are ideal. When we go from one of these hives into one of the colonies in quadruple packed cases we find the cluster not formed but scattered; but the bees under the glass covers seem to be perfectly healthy, and appear to be just about as they look in summer. One thing we know is there are a good many more bees in front of the single-walled hives than those that are packed. This fact is plainly noticeable. It is easy to see that there is a continuous decimation of the unpacked colonies; and if this continues long, the balls of bees will grow smaller and smaller, and finally die.

As previously related, we have sixty colonies packed in quadruple packing-cases at the Blakeslee yard. The colonies in diagonally opposite corners of the cases are covered with sheets of glass the full size of the top of the hive not sealed down. The other

two colonies in the same case, also diagonally opposite, are covered with wire-cloth screens, the same as are used in moving the bees in summer. Over this screen is placed a sheet of burlap, and over the whole about ten inches of planer-shavings.

It will be readily seen that we have a condition of semi-sealed covers in one pair of colonies, and full upward ventilation for the escape of moisture for the other pair, both in the same case. Over the colonies with upward ventilation we find moisture in the packing. Over the hives covered with glass there is no such moisture. The relative difference between the two sets of colonies is not great; but the difference, so far as we can determine, is in favor of the semi-sealed or glass covers. Of course there is no particular merit in glass other than it affords us observation without much disturbance, the same as through the wire cloth.

Our Mr. Rea says that when the weather is extremely cold he has observed repeatedly that the colonies in these cases having upward ventilation during and between the cold spells, with the mercury around zero, will form into compact clusters, while those under glass are nearer the top than the clusters that are less compact. It seems very clear to us that the semi-sealed cover makes a warmer housing for the bees. We shall give reports from now on till spring of the relative conditions of the bees in all the various packings.

N. B.—Saturday, Feb. 13, was warm and balmy. The bees flew as though it were spring. The colonies in the large packing-cases were examined, and found to be in excellent condition. There seems to have been no bad effects from the clogged entrances as mentioned above. A few colonies were opened, and we found the queen just beginning to lay a few eggs, evidently from the stimulus of the warm day and the consequent activity of flying. We did not find brood in all stages as we expected. It is very evident that they did no brood-rearing during the extremely cold weather, in spite of the fact that they were so warmly housed.

The cellar bees are becoming a little restless, and a few more of them are showing signs of dysentery. All those that were spotting the alighting-boards at the entrances of their hives were placed out on Saturday and given a good cleansing flight. We are now waiting for a warm day when they will all be hustled out and allowed to clean up.

Later.—That warm day came Saturday, Feb. 20, when all the bees were carried out for a good fly.

Dr. C. C. Miller

STRAY STRAWS

Marengo, Ill.

R. F. HOLTERMANN, p. 143, you say you never had combs melt down in hives with fence around. Years ago I had them melt down in dense shade with no fence, only close shrubbery; but my entrances at that time were $\frac{1}{2}$ inch or less.

ANSWERING a Wisconsin correspondent, I may say that my bees in the cellar are never entirely quiet. There is always at least a gentle murmur, something like a soft breeze through pine-trees. I doubt if it's possible or even desirable to have utter silence.

MR. EDITOR, are not you and T. H. Holmes talking about two different birds, p. 38? The bee-martin, or king-bird (*Tyrannus tyrannus*), as you say, is a bee-enemy; but the purple martin (*Progne subis*), the one that lives in martin-houses, is not, I think, an enemy.

GLAD to know, Mr. Editor, that you've taken on the grapefruit "habit," p. 144. I'm living with two "grapefruit fiends." They take it every morning "reg'lar," and other times when they feel like it. It's cheaper than medicine, and a heap easier to take. We don't spoil it with sugar, either.

"A CURIOUS thing about the alligator pear is that it is worthless if permitted to ripen upon the tree," but must be "laid away in a dark place to mature," p. 170. Not so curious either, seeing it's the rule with all pears, except Buffum and a very few others. Always pick pears fairly green, and ripen in the dark.

"HELLO, Poppleton! you've got the same old phiz, haven't you?" That's what I said when I opened up to the pictures, pp. 144-5. It is said, p. 146, that he has followed the Long-idea plan these many years "almost all alone." True, if you confine it to this country. But he has lots of company in Europe—good company too.

W. C. MOLLETT, p. 165, because you disturbed bees in winter and they outlived it, don't count too safely on it always. I've had them live after such disturbance, and I've had them die, with pretty clear proof that the disturbance killed them. A few pages earlier (p. 134) the editor says: "A broken cluster, then, in cold mid-winter is a very bad sign. It is evident that the bees are demoralized and the end is near." And disturbing the bees is likely to result in "a broken cluster."

J. L. BYER, p. 97, you have little fear of American foulbrood, but dread European

foul brood. Just the opposite here, perhaps on the principle that we dread the unknown. At any rate, in 1913 I got the best average yield of my life, and in 1914 an average of 70 pounds when all about me was failure, and in both years European foul brood was in my apiary. If ever European foul brood makes you a visit, I prophesy you'll learn two things—that requeening with good Italian stock is not a remedy but a help, and that there are other remedies worth using.

GARDENER B. WILLIS thinks decoy hives must be set in a very conspicuous place, p. 80. With me I don't believe any place is better than right in or about the apiary. Last summer my assistant put a decoy hive up in an apple-tree in the most orthodox manner. It was let severely alone, while nearly every year one or more swarms from outside enter empty hives in the apiary. Hardly a day in summer but scouts may be seen at empty hives, no doubt from colonies in the apiary; but as we are constantly thwarting them they never get beyond the scout stage. Outside bees do.

THE long deadlock in the Illinois legislature since the first of the year still continues. There are four camps, the wets and the dries, in each of the two parties, and no candidate for speaker can get a majority of votes. The leaders of the two parties want to ignore the wet and dry question, and the leading wets and dries want to ignore party lines, and so they get nowhere. Latest prospects are that a bi-partisan combination may elect a wet speaker—possibly a good thing. The issue would then be squarely made, and it might bring state prohibition sooner than any other way. [We note from a late paper that this is just what took place.—Ed.]

GLEANINGS is to be congratulated on the stand taken about advertisements for queens, p. 9. One thing needs to be said that budding queen-rearers don't always think about. A advertises that he can furnish certain queens at a certain time. B sends an order with the money. B waits past the time, but no queen. Then he writes. A replies that he's behind orders, and if B can't wait money will be returned. Then A thinks he's not at all to blame, and says he's done the best he could. But the delay and disappointment may be more than the value of the queen, and A is to blame for agreeing to do what he couldn't carry out. Honest advertising is coming to the fore, and it should be honest in every respect.

NOTES FROM CANADA

J. L. Byer, Markham, Ontario

J. E. Crane hints that it takes great care to make hard candy that will give perfect satisfaction, while A. C. Miller says, page 977, Dec. 15, "any lively youngster" is supposed to be able to do the trick. How do you feel now, Mr. Crane?

Personally we had no trouble making "hard candy;" but the trouble was that it did not suit us, or, rather, the bees, after it was made.

When the National convention was held in Detroit a few years ago I had the pleasure of meeting and conversing for about half an hour with the late Mr. Bingham whose death was chronicled in GLEANINGS for Dec. 15. My first and last personal meeting with him has always been remembered with pleasure, as I was impressed with the fact that he was a real gentleman—one of nature's noblemen. Steadily we are losing our old landmarks of beekeeping; and since I have had the pleasure of attending conventions—not so many years either—it is rather sad to recall some of the names and faces of men we once learned to respect and in many cases really loved.

February 8.—Moderately cold. We are having fine winter weather, with no extremely cold snaps, for the past four weeks. There are mountains of snow in roads and other exposed places, while I should judge we have about 18 inches on the level. This looks good for the wintering of what little clover we have, as well as the winter-wheat crop—the latter, no doubt, more important at the present time than the clover, as the cry to the farmers during this awful war period is, "Produce more wheat." Bees have had no flight, and of course may go six or eight weeks yet before having a chance to cleanse themselves. Prospects are none too good for wintering, as no late flight, small clusters, and poor stores combined in some places do not make best conditions for the bees. A few colonies in my own yards show unmistakable signs of dysentery, which is bad here in Ontario for this time of the year.

Some time ago the editor rather jollied me for wondering why beekeepers in Ohio and other places in the same latitude have trouble sometimes in wintering their bees outdoors while here in Ontario, where we often have a period of four months or more when our bees never have a flight in the

majority of seasons, we have fair wintering. The main "jolly" came in because I referred to Ohio as being "warmer" than it is here. Of course I was told all about those damp cold winds off the lake, and the changeable weather, and the opinion was really given that bees have a better time up here than they have further south. Perhaps they have sometimes; but how about a season like this? As before stated, our bees have had no general flight after Nov. 1. Clusters are smaller than usual, and in many cases some inferior stores are in the hives. As a result, as already intimated, our bees need a flight badly, and there is just a bare chance that they will not get one for weeks yet. A friend not far from Medina, O., wrote me early in January that his bees had a number of good flights in November, and also had two or more splendid flights late in December. I have had no word since; but I suppose that, during the mild spell in January, the bees would fly freely again in that month. Now, won't the editor admit for once that he lives in a "warmer" climate than we do here in Ontario?

As to those big quadruple cases you are trying out, of course you will get good results—no question about that, as they are used by a number of our very best men in Ontario as well as in other places where the winter grows very cold. As a rough guess I would say that half of the bees wintered outside here in Ontario are thus housed, as men like Holtermann, Sibbald, Miller, and a number of other extensive beekeepers use the method exclusively. In the face of all this it may seem like presumption on my part to say that I do not like them, and much prefer the single-colony hive, permanently packed. We are told that, with four colonies together, the heat will be more conserved, and that the bees will winter better than in the single-colony packed hive. While it seems reasonable, yet in my experience this so-called advantage is simply a "talking-point" as an agent would say. After wintering dozens of colonies in single cases year after year in the same yard beside cases holding two and three colonies each, as I had at this place, I never could see a bit of difference in results. The large cases are so bulky that it is almost imperative to have a man with one to do any changing around; and as I am usually alone in the yard during spring and fall, the single hive, double-walled, is the one I want. And

yet I will have no quarrel with the fellow who wants to winter four (or twenty-four, for that matter) in the one case.

Candy-makers tell me that it is a necessity to have a candy-thermometer in order to be sure of having a uniform product one time with another; and in this connection I might say that, only a few days ago, we received 25 pounds of candy made specially for bee feed, from one of the large confectionary firms in Toronto. This can be bought for about 10 cts. per lb.; and if it is as good as I have been told it is, I would rather pay that price than make it myself. With J. E. Crane I think candy-feeding is more of a fad than any thing else, and I seldom have any need of it since good syrup answers all my purposes nicely when bees are short of natural stores.

On page 46, Jan. 15, old covers are mentioned as used for alighting-boards in front of those big cases shown on the cover page. I'll tell you something better than that, at least for our locality, where snow and ice pile around the winter cases during winter. Have no board in front at all, and leave a perfectly straight hive-front right down to the ground. With a sloping board up to entrance, snow and ice, particularly the latter, will often be likely to give trouble, and I find the straight front very much preferable. Of course the hive-stand fills in space directly under the front of the cases, so that there is no danger but that chilled bees can crawl up just as well as they could with a regular alighting-board.

F. M. Baldwin asks on page 67, Jan. 15, if any one has had experience in introducing queens by first daubing them with honey and then placing them right with the bees. Like many other new (?) ideas this one is as "old as the hills," as they say. I remember seeing my grandfather do this when I was but a wee kiddie. I have used the plan once in a while myself, generally when coming across a queenless colony at an outyard, and when I had a queen to introduce and was in a hurry. As nearly as I can remember correctly I have an idea that as good results were obtained on the average as with any other plan; but it always seemed a rather mussy way in which to treat a nice queen. After all, it might be as good as any way yet given, and no one can say but that the plan is easy. There is no danger of the beekeeper not following directions implicitly, and thinking he knows better than the originator.

The push-in-the-comb-cage method of introducing queens, page 922, Dec. 1st, is as "old as the hills," but nevertheless one of the surest plans ever given to the public. My grandfather used the plan at least forty years ago—probably longer, and some of the original wire cages are still to be found. He made the cages larger than those commonly used, many of them being from four to six inches square. We always aimed to squeeze in the sides of the cage so that honey and hatching brood would be covered. In a day or two scores of young bees would be hatched and free with the queen; and I have often found every available empty cell filled with eggs before the queen was allowed to run at large. But, good as the plan is, we rarely use it now unless we wish to be very careful about a particular queen. Why? Simply because of quite a lot of work; and I am afraid that this feature, coupled with some other objections, will cause the plan to be rejected by most amateurs, even if it is recommended, instead of those methods of introduction now in vogue. The queen must be taken out of the cage. Most beginners will dread that operation to start with. Even when working in a closed room, which is imperative, now and then a queen will get away from the cage to the window, even if she does not happen to get behind some furniture. This means catching the queen, and this operation is again dreaded by very many, as, in their eagerness not to hurt her, they are all the more likely to do so owing to nervousness. Then the comb of brood and honey must be taken from the colony. Many amateurs would dread that operation too. The queen must be placed on one side of the comb alone, and then the cage must be placed over her, the sides of the cage being pressed into the comb right to the septum if one wishes to avoid having the bees liberate the queen too soon. In pressing the comb in I have known it to be done so forcibly that the cage would "press" the queen to death, especially if the comb used was a very old one and tough with many cocoons.

Assuming that all the foregoing difficulties have been overcome effectively, in three or four days it will be necessary to examine the comb; and if the queen is not already released, punch a hole from the opposite side of the comb or lift the edge of the cage. All these details are given to back up my contention that the method will never be accepted by the majority of those who buy queens when other plans, although not as uniformly successful, are fairly reliable and much more easy to practice.

BEEKEEPING IN CALIFORNIA

P. C. Chadwick, Redlands, Cal.

The condition of the sages is much better than I had hoped for.

Prof. Cook at our state convention said he had no doubt that Adam and Eve had bees in the garden of Eden. Mr. George Emerson asked what material Eve made the bee-veils of.

While we are having raisin, orange, and grape days, each of which is designated as a day for every one to eat the certain one of these commodities in question, why not include honey?

A gentleman from New York city was transferred to our local postoffice force. One day the subject of honey came up, and the other employees were surprised to hear him say he had never tasted it.

There is nothing that will describe the weather conditions of the present better than to say that California is now being drenched. The rainfall to date, Feb. 13, is above normal, with an average of nearly 15 inches.

Do not try to save fertile-worker colonies. Unite them with other colonies that need the bees. This may be done quickly and safely by setting them on top of other colonies with a sheet of newspaper between the two. The paper will be removed by the bees, and perfect harmony prevail.

A colony containing a large amount of bees at this time in the season can often be used to equalize the force of a less populous colony by changing it to the latter's hive-stand. This plan should not be used so late in the season that it may interfere with the working force of the stronger colony.

J. L. Byer complains of his bees not having a flight since in October. It is my opinion that our California bees would be a little more numerous during the winter if they were confined more closely to the hive. The loss by chill would be greatly reduced. To-day, Jan. 23, the temperature was just at a point that encouraged the bees to leave the hive in quest of stores, which are available to some extent; but many were so chilled that they were hardly able to complete the return flight. In fact, on the

cement walk over which a part of the flight was directed I found several cold and stiff, unable to reach the hive.

If not already done, the queen-excluders should be removed to allow the queen all of the room in both chambers for laying. Replace them ten days to two weeks before you expect to extract, care being used to avoid shutting the queen down in a honey-bound brood-chamber. She should have all available room that ten frames will give, for laying. If honey is coming in freely, and the side combs contain much honey, place them in the upper story and insert full sheets of foundation in their place.

As to whether or not it is profitable to save bees from bee-trees, Mr. Elias Fox takes occasion to say that my ideas on this subject were guesswork. Badly mistaken, Bro. Fox. I should not be surprised if I have not cut as many bee-trees in the East as yourself. Besides I have dug them out of rocks, taken them out of houses, trees, transformer boxes, chimneys, and from under houses in this state. Yet, counting every thing, I believe I am the loser. It is an easy matter to make a success of cutting from trees if you are going to take them home as you describe, and put them on frames of sealed honey. There is a stubborn idea in my head, however, that I could cut out four or five nuclei from my own hives, with as good results, while you were cutting your tree.

Mr. L. W. Brown, page 126, Feb. 1, says: "Out in California is a beekeeper who has kept bees (as well as moths) for over thirty years in the same yard." Just one, Mr. Brown? Well, out in California are some of the most progressive beekeepers in the world who do not take a back seat for anybody. California is a state filled with beekeepers with large apiaries, and richer in experience, on the average, than those of any other part of the United States. California has less moth per colony than most of the eastern states, for the reason that beekeeping here is a specialty, and not a side issue that receives attention after the rest of the farmwork is attended to. We have some dirty, sloppy, careless beekeepers the same as may be found anywhere, but they are the kind that come and go rapidly. The beekeepers worthy of the name are here to stay, and are not harboring moths.

CONVERSATIONS WITH DOOLITTLE

At Borodino, New York.

DIFFERENT FEATURES TO BREED FOR

"I have been thinking about breeding bees for certain purposes. As the flora of our country is not the same everywhere, should not each locality breed strains of bees which are not only adapted to the climate, but also adapted to the flora of that section?"

This is something I think I have never heard spoken of or written about. I know that one strain of strawberry-plants will do well in a certain locality, yet be of little value in another, and that there are very few which are adapted to all sections of North America. Therefore the wise small-fruit raiser will test the different varieties till he finds those which thrive to perfection in his immediate vicinity. I am also aware that the Italian bees will prove successful in times of certain bloom which the blacks consider hardly worth noticing, while on both clover and basswood bloom there seems little difference in favor of either. Quite a few seem to think that the blacks are superior in buckwheat bloom; but after a careful watching, covering a long term of years, I fail to see any material difference. Then there seems to be a difference in different colonies in the same locality as to a successful outcome at the end of the season; but the question is, whether a strain of bees reared and bred for central New York, to as near perfection as possible, would prove less perfect in their nectar gathering in Iowa or California. This is something regarding which beekeepers have rarely if ever expressed an opinion. Is there a reader who can give us any light?

"If we are to develop hardiness in our bees, can we of the North afford to use imported or southern-bred queens?"

This has often been asked me by correspondents. I do not think I have ever written on this for publication, as I did not wish to say any thing that might injure our southern queen-breeders or throw "cold water" on those who consider imported stock superior to queens we already have in this country. It is one of the laws of nature that, the further north or south of the equator any animal or plant can live, the tougher and hardier it becomes. Bees are no exception to this rule. Years ago, before I practiced cellar wintering, I found that both imported stock and that reared in the extreme southern portion of the United

States would be affected by dysentery two to four weeks sooner, in a long cold winter, than would that reared in our rigorous climate for a term of years. But when it came to cellar wintering (my custom for the past thirty years) I could see little difference.

"Which is better to breed from—thoroughbred or crossbred stock? Is not the thoroughbred liable to be bred 'in-and-in' till the strain weakens?"

When bees are crossbred to improve the stock, there is no way of knowing if the crosses are pure or not; and new blood could be infused into them without its being known and to their injury. This objection is insurmountable unless some way can be found to fertilize the queens other than the natural way. By cross-breeding we are just as likely to get the bad qualities of both breeds in the cross as to get the good ones. If I am right, the general improvements in our bees which so far have been made have been attained by taking one variety and improving it by selection, without any cross-breeding whatever. In this way different strains of honeybees can be produced with one or more features. Thus one strain could be produced especially to secure extracted honey—mere honey-gathering its particular feature. Another strain could be produced that would also have comb-building as a special feature: This would be the one for the comb-honey producer, especially if white capping of combs could be added. Breeders have worked along this line so that there are Italian colonies now in the United States that cap their section honey very nearly if not quite as white as do black bees. Such breeding does not seem to injure them.

"How about beauty? I admire beauty; but would not wish it to the detriment of other qualities."

Although beauty is not one of the most important qualities of a bee, I have noted during the past quarter of a century that nineteen out of every twenty persons, no matter whether they prefer the dark Italians or not, will stop before a colony of golden Italian bees and express their pleasure. Beauty is an important factor in human enjoyment. This world was created in beauty. We see the firmament arched with the rainbow of beauty, and at night the heavens are decked with "starry gems" of beauty. The beekeeper who appreciates beauty in his apiary is generally the successful apiarist.

GENERAL CORRESPONDENCE

BEEKEEPING ON THE APALACHICOLA RIVER, FLORIDA; HOME-MADE HIVES

BY E. R. ROOT

Last spring, while I was visiting our boys who were managing our bees at Randlett's Landing, I took a number of excursions up and down the river with Mr. Marchant. On one of these trips I visited Mr. R. L. Tucker, who formerly owned Randlett's Landing, where he kept bees for several years. He has since carried on the beekeeping further down the river. The weather was cold the day of my visit in March, and a good warm fire in his workshop, even if it was in Florida, seemed very comfortable. I did not have with me my camera at that time or I should have been very glad to give you another picture of him in his present location. I showed his apiary at Randlett's in *GLEANNINGS*, pages 81 and 82 for the year 1912. It is sufficient at this time to say he is one of the old-timers. He has studied carefully all local conditions, and he has apparently made a success of the business.

On another one of these excursions up the river I had the pleasure of meeting an Ohio beekeeper, a retired business man of Toledo, who spends his winters in Florida keeping bees to the extent of several hundred colonies. When Mr. Marchant and I arrived there he was out in his "workshop," which was outdoors, where he was busy making hives with the aid of

a single-cylinder gasoline-engine which he had taken from an old Cadillac automobile. Lumber is cheap down in this country; and while it is not equal to white pine for hives, nor as light to handle when made up, it does very well. Fig. 1 will show his rig.

In this connection it is proper to remark that an old discarded automobile will often furnish a fairly good engine, even though the running-gear is completely worn out or out of date. Some of these old single-cylinder motors, such as are found in the Cadillac and the old Olds, make very good stationary

FIG. 1.—F. W. Summerfield's beehive shop driven with an old single-cylinder automobile engine.

engines; at least Mr. Summerfield, who is of a mechanical turn of mind, was getting good service out of his old Cadillac. When one of these engines is detached from the automobile frame and radiator a substitute of course must be used for cooling the water. A common barrel with proper connections, as shown in the illustration, does the work very nicely.

Our friend is rather fond of machinery and boats. He has a regular gasoline-cruiser which he brought from Toledo in which is mounted an up-to-date four-cylinder four-cycle automobile engine. When he went to Florida the first time he put his cruiser, Fig. 2, on a big flat car, and he and his family rode in it all the way to the nearest point where they could get into the river. Then the boat and all was put into the water, when he and his family went the rest of the

FIG. 2.—Summerfield's gasoline-cruiser in which he and his family went from Toledo by rail and water to Apalachicola, Fla.

FIG. 3.—F. W. Summerfield's apiary on the Apalachicola River about twenty miles from Apalachicola.

way on their own power. They cruised here and there, and finally selected a location on the Apalachicola River about 20 miles from Apalachicola. I do not know, but I rather imagine that traveling in a cruiser by rail is not so bad as it might seem; and the expense, Mr. Summerfield said, was not so very great either. This cruiser was equipped with all modern conveniences, so that he and his family could ride, eat, and sleep in it either by rail or by water. This is a great scheme. The wonder is that more beekeepers do not travel that way.

If one can afford it, a cruiser on a good river with plenty of bee range means pleas-

ure and profit. He can establish outyards, and go and see them from time to time. He can haul the bees from one point to another, eat and sleep on the cruiser with his family, and if he does not finish up his day's work at any particular yard he does not have to hustle off to get back.

I have had a little of cruiser life myself (see last issue), and I must say I like it. Some day when I have more time at my disposal than I do now, and I can afford it, I propose to own a cruiser and operate it in Florida. I say, *when I can afford it*. A good cruiser runs up into money—anywhere from \$2000 to \$50,000. For a very

FIG. 4.—F. W. Summerfield, his wife and daughter, and two helpers.

good reason I could not, if I would, go very much beyond the lower figure. But, to return.

Fig. 3 shows Mr. Summerfield's yard of bees where he had last spring at least some 300 or 400 colonies. As is the custom in that part of the country the hives are up on platforms or hive-stands. The principal reason for this is to get away from the ants that are very destructive there. In addition to this the ground is cleared off even and smooth, for ants are particularly fond of getting under some old boards, old stumps—anywhere that will furnish a safe harbor.

You will notice how nice Mr. Summerfield keeps his yard. He and his family and helpers, Fig. 4, seem to thrive in this South-land country. He himself is the second man from the right. Mrs. Summerfield is at his left, and his daughter Hester is next to her. The two other men are Sidney Faust and Guy Gallop; but which is which, my notes fail to reveal.

Mr. Summerfield said to me that I might be disappointed in the locality. He had come down there for his health and pleasure as well as for business. While this is a wonderful bee country it has its serious drawbacks. When I met him at our field day at Medina last summer (for he comes back with his family every summer) he asked me how our Apalachicola venture paid out. I had to admit that it cost us more than we got back; but that the experience was worth all it cost.

"I thought so," said he, with a significant smile. "The only way a man can make bees pay in that part of the country is to go

himself and do a large part of the work. To hire it done as you did is quite another proposition."

He succeeded fairly well, and secured a fair crop of honey, and came back with a carload of *two-story* colonies. Our boys thought when he started north this would spell disaster, as it did not seem possible to ship such big colonies so far, but Mr. Summerfield assured me at our field-day meet he got through with very little loss.

In regard to the matter of increase, he differed with Mr. Marchant in regard to the best way of making it. Instead of putting on upper stories and forcing the bees *above* for increase, he puts the extra story *beneath*. This is his argument:

SUMMERFIELD'S PLAN OF INCREASE.

Heat rises. If a story of empty combs is put beneath instead of on top, the heat will stay with the brood *already started*. As the strength of the colony increases, the heat will work downward. *The queen will follow no faster than the bees can take care of her brood.* On the other hand, if empty combs are placed on top the heat will desert the brood in the lower story, and rise into the upper. This will compel the field forces to stay at home to help hold the heat around the brood in the lower story. Mr. Marchant admitted that this might be true, but thought that with intelligent manipulation more rapid increase could be made on the other plan. Apparently both men succeeded in making fairly good increase. The Summerfield plan might be the safer one for the average person to follow, but perhaps the increase might not be as great.

WINTERING SUCCESSFULLY ON ASTER HONEY

BY HENRY PYATT

In my location asters are the main fall crop, with goldenrod supplementing. My bees stored some of the whitest-capped and nicest-looking honey of this variety one would want to see last fall. One hive filled a 28-section super in ten days besides the brood-nest. Every cell and the sections were so they could be graded fancy. I depend on it for wintering almost entirely.

Last winter my loss per hive, by count, amounted to almost 200 bees. This winter it will be somewhat heavier because they have had only one little flight since Dec. 1.

I winter in double walls with about 1½ inches of ground cork in between; contract the entrance to ¾ x 4 inches; take out two or three frames from a ten-frame or one or

two from an eight-frame, and spread the middle frames apart, or those where the cluster is, so that there can be two or three thicknesses of bees between the two center frames. I leave the rest of the hive open—that is, I don't fill up any inside space with packing. The frames fill the rest. Then a thin super cover sealed but with a place for a Porter escape is tacked over with wire cloth. Lastly I use a burlap bottom tray with four inches of ground cork. This ground cork is ideal. It holds the warmth of the cluster, and yet lets all moisture escape.

I have opened hives when the temperature was about 30 degrees, and found the bees spread over five frames. Except in extreme

weather they are at the bottom of the hive where they should be.

My hives are very seldom moldy or wet in winter, and only occasionally will a little water trickle down inside. A telescope cover fits down over all. Two gable holes one inch in diameter have been bored in for ventilation. My idea is that a slow upward ventilation to draw off any moisture is what is wanted without creating a draft, and yet something that will hold the heat of the cluster.

I am right in the heart of Pittsburg, but in the residential section, where every vacant lot and hillside has its quota of sweet clover, aster, and goldenrod. Besides there are many basswoods and linden trees. Then three miles in two directions will get the bees forage in the hilly countryside. I

never traced any, but imagine they make some long trips.

From four hives last year I got 75 lbs. of comb honey, and 120 lbs. in shallow frames. Besides, I had two swarms, and started five nuclei of one to three frames each, which I sold. I have never had any disease but once, and I am not sure about that. I soon got rid of the hive that had it.

I have several friends, young and old, that have bees here that they got from me. I try to interest them in up-to-date beekeeping. I even gave some to two parties because they were enthusiastic boys, and wanted something to do. Now they can handle the bees well.

If you have as good success wintering on aster as I have had you need not worry.

Pittsburg, Pa.

A WINTER IN DR. MILLER'S BEE-CELLAR

BY C. C. MILLER

An intended visit to Washington, D. C., a year ago last fall, made me want to cellar the bees as soon as it would do, so they were taken in Nov. 8, a little snow being on the hives, but no attention was paid to that. In the evening I went down cellar to see how quiet or noisy the bees were, and was amazed to find one hive lying on its side, without cover or bottom-board, and the frames partly out of the hive. The whole row from which it fell was like "a bowling wall," several piles just ready to topple over. I summoned aid, and we lifted down perhaps 25 or 30 hives, and returned them in proper order. Incidentally we got one of the worst stings of our lives. Evidently the bit of snow melting on the covers had made a toboggan.

Moral.—People who use zinc covers should sweep off the snow before taking in cellar.

The family started for Washington Nov. 11, leaving in the house a cousin and his daughter, thoroughly trustworthy, but inexperienced with bees. The bees did probably as well as if we had been at home; but the weather was unprecedentedly warm, and it would no doubt have been better if they had been taken in a month or more later.

On reaching home, Dec. 19, I went down cellar with some anxiety as to what I might find, but found nothing alarming. The bees may have had a pretty warm time of it, *but they had had good air.*

The thermometer in the cellar was a rickety old affair, and I got a new one, a Taylor,

guaranteed. Since its installment I am suspicious that the old one had reported the cellar warmer than it really was. At any rate the cellar seemed cooler with the new one. Following is a record for several days in the month of January, temperature being taken on the morning of each day. The first column gives the day of the month. The outside cellar-door is a double trap-door, and the second column shows how many inches high the one leaf was raised. Of course the "0" means that the door was closed. The third column gives the outdoor temperature, and the fourth the temperature in the cellar.

Day	Door	Temperature outdoors	Temperature in cellar
January 12....	2	1	45
January 13....	6	12	46
January 14....	0	25	43
January 15....	30	29	47
January 16....	30	33	46
January 17....	27	30	47
January 22....	6	8	42
January 29....	36	31	53
January 30....	6	16	46

Some of those figures do not appear very consistent. Jan. 12, with the door open 2 inches, and only 1 above zero outdoors, it was 45 in cellar. Jan. 14, with the temperature outside 24 degrees warmer and the door shut, one might expect it several degrees warmer in cellar; but instead of that it was 2 degrees colder. To make the table complete, or, rather, more nearly complete, there should be another column giving the velocity of the wind. Jan. 14, the closed door and the warmer weather outside were more than counterbalanced by a strong wind.

Hives taken from the cellar, and placed on the summer stands.

There was another disturbing factor, the furnace. It was in the outside room, into which the outside door entered, the bee-room adjoining, the door between the two rooms being open practically all the time. It will be easily understood that the hotter the furnace the warmer the bee-room. Really that is as it should be, for the colder the weather the more need of heat in the furnace-room to keep the bee-room from being too cold.

With February came colder weather, going one day down to 14 below, although that is not so very cold for this locality.

Feb. 18 I swept up the dead bees for the first time, after the bees had been in 102 days. I think I never let them go so long before, and do not commend it as a practice. The bees swept up weighed 12 pounds and 9½ ounces. I had brought from Washington, the gift of my son, a superb pair of scales, so delicate as to weigh a milligram, or a thirty-thousandth of an ounce. I took 15 dead bees, and they weighed 620 milligrams. According to that there were about 138,000 bees swept up, making a mortality of about 1366 per colony.

I am sorry to say I do not put entire reliance on those figures. According to them there should be about 10,000 bees in a pound, while the A B C and X Y Z tells us there are 4500. It should be explained that the bees swept up were not entire bees, but merely the remains of what the mice had been banqueting upon for more than three months. That would still leave the figures reliable provided the remains were uniform.

Unfortunately they were not. Most of them, to be sure, were. The heads were eaten off and the insides scooped out. But there were a few with scarcely any thing but the wings left, and of course a very few not yet touched by the mice. Added to that was the fact that the bees were not all swept up clean, for some would be under and between the piles. I suspect that the 15 I weighed were heavier than the average; but if I might be allowed to guess I should say that a mortality of 1500 per colony would be nearer the truth.

While sweeping up the bees it was by no means a pleasant surprise to notice that No. 78 had starved to death. I say "notice," for you don't need to examine carefully in such a case, but can tell by the first glance at the bees outside. It would be hard to describe in words, but is the easiest kind of a thing to recognize by the peculiar appearance of the dead bees at and about the entrance when a colony dies of starvation in a cellar. No. 78 was one of the biggest and best colonies; and when a colony has filled a big lot of sections it is generally needless to examine whether it has looked out for itself. But No. 78 had stored in extracting-combs, and I suppose I've got to learn that such a colony is not as safe for winter as one that works on sections.

TROUBLE FROM WARM WEATHER.

March 14 came a very warm day. At 1 P. M. it was 56 degrees outdoors and 53 in the cellar. At 3 P. M. it was 60 outdoors

and 54 in the cellar. The bees were a little noisy, and there was a slightly disagreeable smell in the cellar. The cellar door was kept closed; for if it had been left open the bees would have flown out of the cellar. At times it is all right to keep the door open, even if a few bees do fly out, for keeping the door shut makes the air foul, and more bees may fly out and fall on the cellar bottom than would fly out with the door open. But when it comes as warm as 60 outdoors, and that toward the end of their winter's confinement, opening a door which admits the light is likely to invite to a general exodus.

I don't think the uneasiness of the bees was because they were too warm, but because the air was foul. Bees ventilate when the air is foul in the hive; but in this case there was no ventilation of the cellar, and so the air of the cellar outside the hives had become more or less vitiated, and ventilating the hive could not have its usual effect. Ordinarily the air outside is colder than it is in the cellar, and so heavier. The heavier outside air forces itself into the cellar through all cracks and openings, much as water would force its way in if the cellar were surrounded by water; the warmer impure air is forced upward and outward, and thus a supply of fresh air is forced into the cellar. But when the air outside becomes warmer and lighter than the air in the cellar, the cold air quietly remains in the cellar, no matter how foul it becomes. If the door should be left open there would be some change, in spite of the rarer air outside. It would be a good thing if I had some arrangement by which a large opening, or large openings, could be made without admitting light. Still better it would be if a stream of fresh air could be fanned into the cellar, as occurs in some city buildings. I have no such arrangement. I can only grin and bear it till night comes.

With 60 degrees outdoors, there was some temptation to think the bees had better be taken out. But there was the possibility that a cold spell might come, and then the bees would be better inside. The cold spell did come, and for several mornings in succession the thermometer showed 16 to 18 above zero. Then the thermometer began to climb again. March 24, in the evening, I opened the door and window wide. It blew hard all night, and rained, and with so much wind I felt easy that the cellar would be well ventilated and the bees quiet. In fact, I forgot all about them till 8:30 next morning. Then I went down to see how nice and

quiet they were with the full light shining in upon them. I was fooled. They were any thing but quiet, and were having a high old time sailing to the window. I hastened to shut out the light, with a feeling that I didn't know much about keeping bees. It was 52 degrees outdoors, and 54 in the cellar. By 10 A. M. it was 54 out and 56 in. All I could do was to wait with what patience I might until dark, when I opened up wide, and by morning they had settled down, and after that the weather was cooler.

WINTER MORTALITY.

As already mentioned, the dead bees were swept up Feb. 18. On five other dates they were swept up, and also after the bees had been carried out, April 13. In the following table the first column shows during how many days the dead bees had accumulated; the second column shows how many pounds had accumulated during that number of days; and the third column shows the daily accumulation.

	Days	Pounds	Daily
Feb. 18.....	102	12.59	1.234
March 17.....	27	27.5	1.02
March 24.....	7	6.75	.964
March 30.....	6	14.75	2.458
April 3.....	4	5.5	1.375
April 13.....	10	28.75	2.875

It will be noticed that the mortality in the first 102 of the 156 days was only one-eighth as much per day as at any time after. That is, perhaps, about the usual thing. I don't know how to account for the discrepancy in figures afterward, especially March 30 being nearly twice as much as April 3 as to daily loss.

MICE IN CELLAR.

Some one may ask why so many mice were allowed in the cellar. There were not many. They were constantly trapped; and yet with the cellar door open there was constantly free entrance from outside. There were not enough so that they did any harm to the combs or bees in the hive, the dead bees on the floor occupying their attention.

BEES STRONG IN SPRING.

Having been brought in so early, and having been in cellar so long without the usual care on my part, I was a little anxious as to what the condition of the bees might be in spring. But they came out bright and strong. April 13 Philo Woodruff and Warren Smith began carrying them out in the morning, with the thermometer at 32 degrees. In 2½ hours the bees were on their summer stands; the mercury went up to 62; they had a glorious flight, and all anxiety about the winter of 1913-4 was over.

Annual conference of the Victorian Apiarists' Association held at the Town Hall, Stowell.

A GLIMPSE OF A VICTORIAN APIARISTS' CONFERENCE

BY E. B. MACPHERSON

As I was a delegate to the fifteenth annual conference of the Victorian Apiarists' Association held at Stowell, July 21, 22, and 23, 1914, I had to travel by train all day and all night to get there; but I was well repaid, if it was only to meet the many beekeepers I made friends with aside from the valuable points of an apiarist's trade one gleans from such meetings.

On the third day of the conference we all drove out in drags and motors to J. C. Liddle's Myrtle Bank apiary four miles from

Stowell. The road out was full of interest to the beekeeper, as different species of eucalyptus were passed and noted, and very interesting discussions would take place as to their value to the bee farmer. As it was winter the bees were practically dormant. A few hives were opened at Mr. Liddle's, and the different races of bees examined.

Wintering bees in Australia is simplicity itself compared with the methods the "Yankees" practice with cellars, etc. In the photograph of Mr. Liddle's apiary you will see a typical Australian method. A piece of sack is put on top of the frames as a mat, and the cover is put on. As long as there is enough honey for the bees they are as safe as man can make them for winter.

After the ladies of the house supplied us with afternoon tea we took a drive through more "bee country," then back to Stowell. Every night of the conference we had lantern lectures by government scientists which were very instructive.

Port Fairy, Victoria, Australia.

Mr. R. Beuhne, government expert, giving a demonstration in queen rearing at Mr. Liddle's apiary four miles from Stowell.

TRANSFERRING MADE EASY

BY LLOYD A. JONES

"Got any bees in box hives?"

"Yep, and I reckon I'll let 'em stay too. I hain't goin' to rip off a side of them hives with the bees in 'em, and cut out the combs and fit 'em to frames, and git all daubed up with honey, and git half carried to eternity by stings."

Wise old man that, who makes such a statement when advised to transfer bees by cutting out the combs and fitting them to frames. But let me give you a little less complicated way, old man, which is also a little cleaner, easier, and quicker. You have probably heard some one speak of the Heddon method. The first thing is to get a good hive with frames, and, if possible, four or five or even six frames of comb in which the bees died the previous winter. Put these frames with the drawn comb into the new

hive, and insert a division-board close to the outer frame. Go to the box hive, loosen it from the bottom-board, invert it, and place over it a box eight or nine inches deep and just the right size to rest on the box hive and leave no bee-spaces.

Take two sticks and practice your Saturday-night drum part in the band on the sides of the hive. After drumming four or five minutes take off the hiving-box; carry it to the new hive, and dump your bees in front of the entrance. Now put on your

Some of the beemen at Mr. Liddle's apiary.

spees, squat down, and watch for her royal personage. The bees will not stay in the new hive without their queen. If you don't see her, march back to the old hive and begin drumming again. When she goes in, sigh a sigh of relief and go back and restore order in the vicinity of the box hive.

After three weeks make your appearance with the same kit you used before, and drum out the rest of the bees from the old hive. Where did all these bees come from? You gave the hive a vacation of three weeks so that the brood might hatch.

If you think you have a good queen in the new hive, use an entrance-guard at the second drive. Dump the bees as before in front of the hive and watch for queens. If you see any, take them and give them to queenless colonies. Now take the combs out of the box hives. A knife and a saw might come in handy here. Some of the combs will be fairly straight, and some will not. If you have any empty frames, bring them forth. Cut out the imperfect parts of the combs, leaving the best parts in the pieces

that you fit into the frames. Take some wire and wrap around the frames to keep combs from falling out, and then put these frames into the new hive into which you have dumped a new lot of bees.

If there is more comb than you can get in that one hive, fit them to some more frames and give them to weak colonies or save them and give to a new swarm. You will probably have some honey left now; but I am not going to bother to tell you what to do with it, because I know you would eat it in spite of what I told you. I like this way much better than letting the bees take it out of the old hive themselves. That is liable to start robbing, especially if weak colonies are around; and my experience has been that the bees make too much of a good thing out of such a proposition. They go into the hive, gorge themselves, come staggering out, tumble out on the grass, and stay until they get over their drunk. They are wasting time, in my opinion. I would rather do that and let them be working in the field.

Litchfield, Me.

A DAY'S JOURNEY

BY E. H. BURTON

If one keeps bees for his own pleasure and profit the information soon spreads through the neighborhood that Mr. So-and-So is a beeman, and many opportunities come his way for advancing the beekeeping cause and helping his neighbors along. Quite frequently some one offers me a beeyard which has been neglected, and which I am expected to take over and turn into golden honey and bees.

Just recently a friend turned his yard over to me to work on shares, and I agreed to transfer the bees into new hives, furnishing every thing, for one-half the bees and one-half the surplus honey that was in the hives at the time of taking charge. By working along this line I have been able to establish several good outyards, and I usually agree to work other yards for half the honey and half the increase if I furnish all the supplies.

As this particular yard was distant some

eight or ten miles it necessitated an early start the next morning if we were to get in a full day's work. The evening before, our spring wagon was placed in front of the bee-supply house, and every thing loaded into it that would be needed. First the tool-case was inspected to see that it contained every thing necessary for transferring and for manipulating hives. This case is large enough to hold the smoker, a hammer, cold chisel for opening old box hives,

Abandoned bees sometimes do astonishingly well.

a long-bladed butcher-knife for cutting the combs loose, a chisel, a hive-tool, a screw-driver, and bee-brush. This case also has a till in which are carried matches, tacks, several sizes of nails, some large hive-staples, etc. We placed in the wagon six eight-frame hives, several extra brood-frames with foundation, splints, extra supers, two lard-cans for surplus chunk honey, feed for the horse, and a water-bucket. We were ready for an early start except to pack up our lunch before the trip.

An early breakfast and we were off at 3:30 A. M. We enjoy these fresh morning rides past waving fields of grain, through shady dells, over bridges whose cool streams below look inviting for a wade in their sandy banks, now slowly up a steep hill with mammoth beech and oak casting their somber shadows along the roadside, and finally to the crest of the hill where old Prince can stop and blow while we take in a panoramic view of a southern Indiana landscape. In the distance

Still sits the schoolhouse by the wood,
A ragged beggar sunning;
Around it still the sumacs grow,
And blackberry vines are running.

Transferring took plenty of smoke.

The bees had built comb on the outside of one hive.

To the south is White River, glistening in the morning sun, and here and there a farmhouse dotting the hillside with smoke lazily curling upward in the damp morning air. Fertile fields lie below us with their long undulating rows of waving corn.

The odor of fried country ham in the cold morning air broke our reverie, and we trotted off to reach our destination at 7:30 A. M.

"We're up against it!" were the first words my assistant spoke on seeing the beeyard. "Blacks!" he yelled, as one took him under the left eye.

A casual inspection of the yard soon convinced us that bee-veils would be a good thing, for we were going to handle some blacks and hybrids that were entire strangers to such things as smokers and modern hives.

We found fifteen very strong colonies in all manner of boxes, kegs, and antique hives, all swarming with little red ants that crawled

up our hands and arms and made us miserable. The chickens and turkeys had made a roosting-place of the shed and tree under which the bees had been placed, and their droppings were six inches deep between the hives. The old foundation on which the hives rested had long since decayed, and the bottom-boards on the old hives had rotted away. Stinkweeds and pokeberry flourished in front of the hives, and the bees were happy in wanton abandon. Stronger colonies one would hardly wish for; and it is a peculiar fact that, where bees are let severely alone, they sometimes flourish surprisingly well.

The first view shows the yard before we commenced work. The second gives a glimpse of one corner of the yard where three empty hive-bodies had been stacked up and the bees had taken possession. One hive with the lid knocked off had an old cloth over the brood-frames, and the bees had water-proofed this

There is a certain satisfaction in cleaning up a hard proposition.

with propolis. This hive had remained in such a condition through the winter, and the colony was strong and healthy.

We removed the hives to the orchard and lined them up against the pickets. The last photograph shows how it looked when we were done with it. We had placed them on good substantial wooden supports with the bottoms about six inches off the ground, with a chance for air to circulate under them. Red ants were effectually kept away.

Washington, Ind.

We moved the hives to the orchard and lined them up against the fence.

STOPPING A ROBBING RIOT

BY ARTHUR C. MILLER

A bee is a reflex machine—er, that is to say, nearly so. She is much like a small boy, always into something; and, like the small boy, must have her attention diverted into other channels if she is to be successfully turned from the mischief-making. You may correct the small boy by a vigorous spanking; but try it on the bee and you will have proof positive that she is a reflex machine.

Last fall I wrote of some experiences in quelling trouble in an apiary, and said that I would give some of the particulars later. Now a friend reminds me that I have so far failed to do so.

The conditions found were these: General robbing was rife, and the bees were fighting mad. A veil was a necessity. There was a swarm out, driven out by the heat and the robbing turmoil. Two colonies were all robbed out, and one had about half of its population killed. Even the brood had been consumed.

The owner and another beekeeper, just previous to my arrival, had searched through these colonies for the queens and pronounced them queenless. When I came on the scene they were decidedly ready for help. Conditions were actually dangerous.

First I shook the swarm into a large box, threw some water over the bees, covered the box with a cloth, and set it in the shade. Then I threw water into the hive the swarm came from, taking off the cover and splashing it over the frames. The hive was then shaded.

The next thing was to stop the robbing, and quickly too. All of the extracting-combs were above escapes, and free from bees. Some of these were rushed into the extracting-tent and the honey extracted. Seizing one of these supers full of wet combs I walked down the whole length of the apiary and back again. The bees poured into the super until it was full of them, and it was then set on a hive floor placed a rod behind the rear row of hives. Another super of wet combs was used in the same way, and then two more. The four were stacked, a cover put on, the entrance reduced to one bee-space, and the worst of the trouble was over. All of the ugly warriors were inside of those very sticky supers. As fast as other sets of combs were emptied of honey they were stacked in the same way, the piles being six bodies high. (The "supers" were full-depth bodies.) Every super was carried out without bottom or top, and the bees were permitted to pile in as fast as they chose;

but once in, and the super on the stack, they could get out only by way of the one-bee-at-a-time space at the bottom. Peace reigned within fifteen minutes after the first super was carried out.

Attention was then turned to the colony that had swarmed. As was suspected, no cells were to be found. The swarm was at once returned, shade replaced, and they settled down to business. The two robbed colonies were the next cared for. A moment's scrutiny of the bees at the entrance of one assured me that they had a queen. The evidence at the other was less positive, for they had lost half of their population; still, I felt pretty sure that the queen was still there. The first stock was opened and the queen was found at once. Two combs of honey were given to it; the entrance was reduced to about one inch, a creosote compound smeared about it, and they were safe.

On opening the second stock it appeared almost ruined. The honey was all gone, all unsealed brood was gone, and much of the sealed brood had been torn open and partly consumed. Over two quarts of dead bees lay on the floor, besides all those on the ground before the hive. The queen was quickly found, and was uninjured. A frame of brood in various stages was taken from another colony, freed from bees, and placed in the front part of the hive right next to the entrance. (All hives in this apiary, about forty, have the entrances parallel to the combs.) The rest of the brood was pushed up against the comb of fresh brood, some of the empty combs removed, and two combs of honey placed in the back part of the hive. The reason for this procedure is that bees will protect brood better than they will honey, or, perhaps I should say, the brood holds the bees close to the entrance, and then they will fight to protect it and their home. The entrance of this hive was also reduced to about a square inch, creosoted, and left. In a few days this stock was nearly normal, though of course weakened.

The psychology of the cure for robbing was to get the bees busy in some other place, and by brief exposure of the wet combs while walking up and down the apiary all of the real persistent and pugnacious robbers were gathered in and permitted to return home only one at a time; and as they of course got well daubed up in those sticky combs they were a long time getting fixed so they could go back.

The diagnosing of queen conditions by

entrance examination is impossible of description; but I can tell you how I learned it. I would dequeen a stock and then sit down and watch the actions of the bees, and the watching might be for an hour or for several hours, and be renewed at intervals for many days. Many repetitions of such procedure shows a lot, provided one has the eyes to see and the ears to hear. This sort of experimental study of bee behavior is most valuable; but, oh how rarely is it used! and how even more seldom do we ever hear of it! One experiment will not suffice. It must be one after another during different parts of the season, and season after

season, and with different strains of bees. Can I always tell conditions within the hive by appearances at the entrance? Frankly, no. But I can most of the time, particularly where I know the normal behavior of my strain and the general standing of my apiary. Under such conditions I can tell enough to save myself from opening any but an occasional hive, and even then a casual glance across the top of the frames is all that is needed to settle the matter.

Try the plan of experimental observation and see if you do not discover a new world in bee culture.

Providence, R. I.

FURTHER PARTICULARS ABOUT THOSE TEN-POUND PAILS FOR FEEDING

BY J. L. BYER

When sending in "Notes from Canada," Dec. 1, I did not think that the item on using the common ten-pound friction-top pail as a feeder would excite any comment, as I knew that here in Ontario, at least, the plan was known to the majority of our beekeepers, as it has often been discussed at our conventions. Imagine my surprise, then, to get letters from California, Texas, Florida, and New York, to say nothing of intermediate points, asking that I explain more fully how we use the pails. So far as I know, I have personally answered all who gave me their addresses; but as some wrote me asking me to describe the plan in GLEANINGS, and gave no address, I am taking this opportunity to oblige the last-named, and at the same time to save me from doing a lot more writing on this subject.

The pails that we get here in Ontario have a lid that presses down in such a manner that, when it is firmly in place, the edge of the pail projects quite a little beyond the flat surface of the cover; and as they are inverted over the bees on top of the frames, this projecting edge allows a space for the bees to move freely between cover and frames. With a perfectly flat-surfaced pail this same advantage could be given by placing small strips of wood under each side.

Now as to preparing the pails, that is simplicity itself. Remove the lid to be used, and place it on a block of wood with the inner side up. With an awl or other sharp-pointed instrument (I have used even a three-inch nail filed sharp), punch 40 or 50 holes in the lid. Preferably have a larger number than this with very small holes than a less number with larger openings. Punching from the inside of the lid leaves a

smoother surface inside, and will insure cleaner draining of the pail.

For use, all that is necessary is to fill the pail with syrup, firmly press in the lid, and then invert pail and all right over the bees to be fed. If you use a double-walled hive with an extension to take roof or super, simply turn back a corner of the quilt; invert the pail over the exposed surface; pack around it if the weather is cool, and the job is done. If single-walled hives are used, place an empty super on top and place the pail inside. If a honey-board is used it will be necessary to have an opening cut in the board and place a pail over this opening. This is an ideal condition for feeding, as all heat is kept in, and it is absolutely safe from robbers, as the pail fits closely on the board.

Nothing is new about the principle of this feeder, as it is simply the old-time pepper-box feeder used in a more wholesale manner. The hives must be fairly level, and the pail-tops perfectly tight, and then the syrup will come out no faster than the bees draw it from the holes. Atmospheric pressure does the rest. As the syrup is drawn away from the bottom of the upturned pail a vacuum is formed, and this keeps the syrup from running out of the holes. In feeding at an outyard, if you wish to give a colony more than ten pounds of syrup at once, simply give them an extra pail and they have twenty pounds—no measuring of syrup nor slopping it over hives, as the pails can be filled inside of a building and carried out as wanted. If the feeding has been delayed till late cool weather, a pail may be placed directly over the cluster, all packed snugly above, and the bees will take

the syrup readily. In fact, while carrying out some experiments in 1912 for the editors of *GLEANINGS* I fed some colonies like this late in December, when the weather was decidedly cold. Some other feeders are no

doubt just as good; but I doubt if any are always just as handy to use and just as easy to get. Try them and see if you do not agree with me.

Markham, Ont.

THE APITRAM; BEEKEEPING WITH THE LABOR LEFT OUT

BY WILLIAM BEUCUS

In beekeeping there is, at present, a great deal of labor wasted. Wooden hive-stands decay, warp, crack, come loose at the corners, and become unlevel. They must be repaired, leveled, and replaced, all of which costs much labor and money and time in addition. When the honey-flow arrives it becomes necessary to go through all colonies to determine what shall be done to prevent swarming. To get to the vital part, the brood-chamber, it is necessary to lift off the supers, and, when the examination is over, lift them back again. When a swarm issues, the supers must again be handled to get to the brood-chamber for the purpose of shaking or brushing off bees. Every examination and every manipulation which involves the brood-chamber is necessarily preceded by a great deal of unnecessary hard work.

When the time comes to remove the crop, still more hard work must be done. It is no fun, even for a powerful man, to handle all day chambers of extracted honey weighing 75 pounds. Some effort has been made to overcome this. One uses a wheelbarrow, another uses a heavy wooden track and a car to run on it; but still the entire crop must be lifted bodily and transported to the car, a distance more or less great, and then lifted off again. There is more heavy work in the fall and more in the spring in moving bees in and out of the cellar.

The apitram, shown in the illustration, was invented primarily to overcome the labor of lifting off heavy chambers of extracted honey during the honey-flow. Incidentally a large amount of other work has been eliminated.

As a hive-stand, the apitram, once it is properly set up, overcomes the labor of leveling hives from time to time. Made entirely of iron it is indestructible—there is no depreciation. It is collapsible, and is, therefore, portable. The removal of a few stove-bolts separates the sections which may be put on to a wagon, when collapsed, and moved to a new location.

Fig. 1 in the photograph shows the apitram just after it was set up. The supports are of wood; but these will be replaced by combined rests and stakes made of iron,

which will be very much cheaper in the long run. To prevent these combined rests and stakes from sinking they will be run through an adjustable galvanized plate which will rest on the surface of the soil.

Fig. 2 shows six colonies in place. The center ones, numbered 29 and 30, face toward the camera, and the two on either side face in the opposite directions. This illustration shows the possibilities in neatness.

Fig. 3 shows how combs may be removed between the rails of angle iron.

Fig. 4 shows the lessertram, as we call it—a contrivance by means of which the brood-chamber is rolled out from under the upper stories for inspection, removal of combs, forced swarming, replacing queens, etc.

Fig. 5 shows the brood-chamber drawn out and examination of combs taking place. Notice that the smoker is hung conveniently near. Two projections of iron, about two inches long, will later be riveted to the opposite side to furnish a support for the first comb removed or for the division-board. In front a part will be fixed for the scissors and the hive-tool.

Withdrawal of the brood-chamber is accomplished as follows: The T, shown in Fig. 2 and also in Fig. 1, just below the easter, is shoved back. This lowers the rear end of the brood-chamber. The lessertram is slid over into place and the hook rolled up until the point is well under the hive-bottom. The wheels are now allowed to roll down as far as they can, which tightens the grip. Two blocks, one of which is shown in Fig. 1, are removed from the tin channels in which they slide, thus lowering the forward end of the hive which now, in most cases, begins to roll forward. With a slight pull the chamber is brought out as far as it will go. As there are two easters at the back of the hive, which run in the tin channels, and as the two wheels on the lessertram are of the roller-bearing type, the chamber sometimes rolls half way out without being assisted. The tin channels make it impossible for the easters to run sidewise when shoving the chamber back. It must go back to the point from which it came.

Wm. Beucus' scheme of locating hives on a steel track so that lifting and carrying supers is avoided.
 Another view of Mr. Beucus' apiary is shown on the cover.

Fig 1701

Fig. 6 shows the apitruck. To use it, the brood-chamber is first lowered. The side toward the camera is removable, which makes it possible to roll up the apitruck and surround three sides of a tier of supers. The fourth side is now replaced, thus surrounding the supers entirely. The levers, a pair on each side, take hold under the supers. Each pair works in unison. A pressure of about one-tenth or less of the weight of the supers is needed to lift them.

The apitram is supposed to be extended into the extracting-room directly to the uncapping-tank. The photograph shows the apitruck in the center of the apitram with a tier of supers on the way. In actual use the tier of supers nearest the extracting-room is run in first. This leaves the track clear for the second tier. Thus one tier after the other is taken in. The wheels in the apitruck are roller-bearing.

No doubt the reader will gaze at the apitram in despair, and remark mentally, "It must have cost a lot of money." But such is not the case. One lessertram, one apitruck, and 160 feet of apitram cost with freight, cartage, labor, money orders, iron, bolts, etc., included, \$46.60. The cost is thus less than 50 cts. per colony. Of course my own labor was not included.

Are we justified in making an outlay of 50 cts. on a colony? Let us see. With the apitram, only brood-chambers are handled during the honey-flow. The time and labor thus saved can be used to handle a great many more colonies. In my own case I think it will be double the number. But this is not all. If the hard work is eliminated, the period of productivity is lengthened.

Man's power to do hard work decreases as his age increases, after a certain point is reached. If the apitram enables a man to produce even five more crops than he otherwise would, has not the apitram paid for itself?

Some may say that facing two colonies the same way, with only two inches between them, will cause the bees to mix and will result in the loss of young queens. I have watched this closely during the season and have yet to find a single lost virgin although several nuclei

were placed on the apitram for the purpose of having virgin queens fertilized. Now as to bees mixing.

In August a colony of black bees on the apitram was examined; and, strange as it may seem, the colony had not a single yellow bee, although the bees two inches from it,

Fig. 222

in a hive facing the same way, were hybrids with yellow strongly predominating. In fact, an entrance close by enables a bee to mark more certainly its own. How do I know this? When a brood-chamber is rolled

out, some of the bees of the adjoining hive endeavor to find an entrance at the back of the hive next their own. They have marked their entrance as one of a pair. With a chamber rolled out they return to one entrance instead of a pair, and naturally shift over one place to the right or the left as the case may be.

Briefly summing it up, then, we may say that the apitram and its accessories secures the following advantages:

It furnishes a hive-stand which, once properly leveled, need not be leveled again.

It eliminates depreciation of the hive-stand and reduces depreciation on hive-bottoms.

It prolongs the producing period of the beekeeper.

It immensely reduces the hard labor in beekeeping, and thus makes the work pleasanter.

It greatly increases the number of colonies one can keep, and thus makes the business more profitable.

It makes the business look more like a business.

It secures the maximum of neatness.

By placing the largest number of colonies in the smallest amount of space it saves space and steps.

Cadotte, Wis.

[We presume that some may be inclined to ridicule this array of machinery, tracks, etc., for doing away with the lifting in an apiary. However, none can doubt the ingenuity displayed in the arrangement considering all its details.

We do not wish to throw cold water on so clever a plan, but there are a few objections which we believe Mr. Beucus himself will recognize after he has tried the arrangement several seasons.

Having the colonies so close together, besides causing some mixing up on the part

of the bees (of course partly done away with by changing every two colonies around so that the entrances face in the other direction) also causes some inconvenience to the apiarist, as it is necessary to stand at the back instead of at the side of a brood-chamber unless the brood-chamber is run out in front by means of the "lesserttram."

We admit that the whole arrangement seems to us rather complicated. Taking every thing into consideration, the time of putting it up, etc., we doubt whether it would bring about an actual saving in time; but that it may be a saving in strength after it is once set up, there is little doubt. In this country, where it is not necessary to locate the colonies in the smallest amount of space possible, it is a question whether it pays to spend very much money on a permanent equipment, such as a house-apiary, for instance, or some such device as this mentioned by our correspondent, for conditions are such that it often becomes advisable to move the bees from one place to another. While this apitram could be moved we think that the labor required would be a considerable item.

In our opinion, moving supers to the honey-house by means of the apitruke would not be practicable, at least in very many cases; for unless the extracting is postponed until after the honey-flow, empty supers must be returned to the hive. If the apitruke were used they would have to be stacked up until the whole extracting were finished, and then returned all at once; moreover, in case of double-story colonies, or colonies with partly filled supers, the upper stories would often be in the way.

After having said all this, however, we believe there are possibilities connected with the plan. If an expenditure of a moderate amount of money will bring about a saving of both time and labor, such expenditure is worth looking into at least.—ED.]

THE BUGBEAR OF SPRING DWINDLING

BY E. S. MILES

When I first began to have the bee-fever, more than twenty years ago, one of the first phrases I heard that came near curing the fever was "damps." A farmer kept some bees in the "good old way" in some boxes in the back yard, and one severe winter a large part of them died. The old farmer, investigating on the first warm day toward spring, found the combs all wet and daubed with honey still in the hive. So, thinking they could not have starved with honey

in the hive, he very properly, perhaps, with his knowledge, said they were afflicted with the "damps."

That word "damps" struck a chill through my apicultural frame, if you will allow the expression, and lowered my fever several points. Why do bees die with some dreadful mysterious malady? Damps? Whew! the name was enough to dampen one's rising enthusiasm. But on second thought it occurred to me to ask myself

whether the person making the diagnosis was competent. If it was really a disease which occurred only in winter, then why not *every* winter?

So the conclusion came that it perhaps was not a disease, but the result of some conditions that might be avoided. So the "fever" advanced until I got possession of three or four colonies of bees, and in the course of time I secured the 1891 edition of the A B C and X Y Z of Bee Culture.

I had just about recovered from my misgivings about the awful "damps," when, in reading this admirable book, I came to the subhead, "Spring Dwindling," under the head of "Wintering."

After looking at the picture of the "blasted hopes" apiary I thought, "Horrors! here is a malady. Now if you're wise you'll go a little slow on this bee business."

By this time I was too far gone to be scared out of the business, so I went on studying and practicing what I studied, to see how it would work for me. But for some time this spring dwindling haunted all my beekeeping thoughts. Some spring I would tell myself, "My bees will get spring dwindling, and I'll be wanting to sell out cheap and 'move to Kansas.'" In the mean time my bees wintered well, came out of the cellar (for after reading the evidence I decided for cellaring) about as strong as they went in, and seemed to have just as much vim and energy in April as in October.

After a number of years I began to question the idea that this spring dwindling is a mysterious and unpreventable thing, whether disease or effect of untoward circumstances. By this time I had found that in actual practice, with me, some things worked out a little differently from what I expected when I read the book. I began to see that, while the book was in the main correct, yet everybody would not everywhere reach the same conclusions by following its instructions; and that when I undertook to do something "according to the book" I was not bound to accept only what results the book led me to expect, but that I could get whatever results there actually were. From that time I really began to learn the ways of our little friends. The book, therefore, was a sort of guide to start me on certain experiments until such time as I should be advanced enough to guide myself.

Well, by the time I had kept the bees several years, and had increased to a small apiary without winter loss or any appearance of the dread spring dwindling, I began to gain confidence; and as I gained confidence the fear of spring dwindling grew

less. By this time I even laughed at the "damps."

So it ran on from year to year. I tested outdoor wintering also, alongside of cellaring. After fifteen years of wintering all kinds of bees in about all kinds of conditions I came to say to myself, "Why, what makes you say, 'I'll do so and so, if the bees winter'?" If you care for your pigs, cows, or horses in a proper manner, don't you figure on having practically all of them next spring? Of course, but they are not bees. What difference does that make? If you have cared for your bees as to feed and shelter for fifteen years, and they have proved it by coming through safely, can you not do it for another fifteen years?

So now I was almost laughing at the phrase spring dwindling—not that it was quite as mythical a thing as the "damps," but fast becoming so.

About this time I stumbled on to the greatest fact in regard to the nature of bees that has come to my knowledge thus far on my apicultural journey. This great fact is the variation in bees. Heretofore "bees were bees." I looked upon them as all alike, to be treated all alike, and to expect like results. It took several years to convince myself that my imagination was not playing me a trick.

But in these several years wherein I was studying this fact of variation I really came to laugh at the term spring dwindling. Yes, I know what beekeepers mean by it now who recommend a certain kind of hive to prevent it, the same as I know what ailed the old farmer's bees when he said they had the "damps," and he wanted a moth-proof hive too to save his bees from the moth-worms, just as you want a chaff hive to prevent spring dwindling. You ask if I mean to say a chaff hive will not prevent spring dwindling. No, I don't. I let those have chaff hives who want them and think they can afford them; but they may or may not prevent spring dwindling. Have you guessed by this time what causes it?

Give my guess—spring dwindling is caused by unfavorable surroundings or poor feed, or both, through the early part of the winter, this causing the colony to reach the season of year when it needs the greatest vitality, with greatly lowered vitality. Hence, instead of gaining in normal seasons, or holding their own in adverse ones, it loses, or spring dwindles, until some cold night finds them with too small a cluster to maintain the necessary heat, and they perish.

Now I hear some one asking, "What has your variation to do with the matter?" Mr. Root, in that old edition referred to, says in

substance that it will affect one part of an apiary and not the rest, or all of one and not another a short distance away. "Some don't seem to be affected by it at all." Is there not variation in bees as to hardiness, good wintering, honey-gathering, swarming, and many other traits? But these people whose bees suffered with spring dwindling and the "damps" thought a "bee was a bee," and one swarm as good as another if it had as many bees.

When I had kept a correct record of colonies for years I began to see that a bee was a bee, and in some cases quite a little more so, and that some colonies would stand a whole lot more adverse circumstances than others without serious injury; and, more, I

found if one bred his queens from these a large proportion would be the same; and that by breeding from a good thrifty, hardy, honey-gathering strain, one would have better colonies to start winter with, and more and better stores. Then each colony would also have more vigor to resist untoward conditions if it did happen to meet them, and, finally, would have more vigor and "grit" to hang on if by any chance the colony does get injured in wintering. So, now, when I hear any one saying, "We had an awful spring, my bees got spring dwindling," I always think of the old farmer whose bees got the "damps."

Dunlap, Ia.

THE ALTERNATIVE: FEED OR UNITE?

BY L. E. KERR

It is not always necessary to feed bees, since for years they go without requiring such attention. Certainly it is never advisable until necessary. It depends upon the nature of the crop, bees, queen, hive, season, and management. For several years we have done no feeding whatever, but have frequently employed the alternative of stacking colonies until the pile is sufficiently deep that the food question among them becomes one only of moving occasionally to the next floor.

In a climate that does not favor close protection, united colonies have often been left to arrange household problems as fancy dictated, and they invariably come out in spring in a condition that argues well for co-operation. With strong colonies, however, and especially where decrease is objectionable, there is a question as to whether it would not be more satisfactory to put at good interest some time and money in keeping integrate and well fed the separate family circles.

When with the modern shallow brood-chamber an occasional colony stores all honey in the supers, to be removed entirely by the inconsiderate apiarist, why should he not in return provide other and ample stores? Otherwise, could he reasonably hope another season to have any surplus at all in those supers?

Should any appear light before flowers bloom, an empty super can be put on, a few pounds of loaf sugar heaped upon the frames, and every thing packed warmly with paper or burlap before the outer cover is again put on. It is the work of but a

moment, and cannot be improved upon for cold-weather feeding.

Bees, unlike their owner, regulate operations at all times in strict accord with the extent of their resources. Unless they go into winter well supplied, their stores by spring will be much reduced; and, above all others, this is the very time they never should feel pauperized.

With the advent of flying weather if any colonies have insufficient means for unhampered brood-rearing, some profitable stimulative feeding can be done. It is best done evenings, and can be gradually lessened as nectar increases. While some speak lightly of slow feeding to induce brood-rearing, it will give greater results.

In small feeders efficiency is embodied in a one-cent self-sealing can having a dozen small nail perforations through the lid. They can be inverted directly upon the frame tops, above the cluster, but are used to greatest advantage over the opening of an escape-board or inner cover. If such a cover is left on during fall and winter, it will be tightly sealed to the hive, and no cold drafts created.

Among all living creatures few instances can be found where nature ordered a faster shifting of generations than is provided in the worker bee. Well within each sixty days, through the summer season, the home is refilled with an entirely new throng of thousands of bold restless toilers eager to let not one moment of their brief existence go unfreighted with some act of devotion to queen and the common good. While with the idleness of winter their life-cycle is somewhat augmented, and a few, perhaps,

never learn menial labor, the older bees are relentlessly but gradually lost to the cluster. Before the flowers of spring bring a welcome reprieve, best stocks are more or less depleted; consequently, to have an active force of young bees ready to replace the few feeble survivors, it is imperative that brooding commence without delay. This will occur naturally only when a plentiful store of honey is accessible. This is always the deciding factor in

profitable and consistent spring feeding.

There is always one time when winter and

spring feeding is in place, and that is when any colony is without stores.

Ft. Smith, Ark.

A FOLDING SPRING PROTECTION

BY H. HARLEY SELWYN

I am sending some illustrations of a spring protection case I have had in use for nearly six years now, and which has proved very satisfactory. The framework holding the heavy grade of roofing-paper is dressed

lumber of $\frac{7}{8}$ -inch thickness, and the four pieces hinge with cheap strong hinges. An entrance-block crosses the front of the hive and holds up the shavings and also keeps the case the required distance from the front

FIG. 2.—It is not difficult to pack each hive snugly.

of the hive. Each colony is packed on its regular summer stand after being moved out from the cellar. The stands are made of 2 x 4-inch scantling, with a graded light board in front. This may all be seen from the picture. Over every thing is a heavy wooden cover which may be built either of rough or matched lumber as you wish.

A special feature of this style of spring protection case is that it can be laid out flat when stored away, and so will take up practically no space. There are 100 of these cases in use in our yard, and they all go in a lean-to not much bigger than 6 x 10 feet.

In one day I have packed a hundred colonies with shavings, and removed them equally fast later in the season when the disagreeable blustery weather had passed.

FIG. 3.—The spring case furnishes ample protection against blustery weather.

The views show, first, the case in parts; next, being placed about a hive; and, lastly, the shavings in and cover on.

BUILDING UP WEAK COLONIES

BY B. KEEP

"Build the colonies up strong and have them ready for the honey-flow."

That sounds good; but how shall I do it? asks the inexperienced person; and many of those not so inexperienced are turning that same question over in their minds, and quietly seeking a satisfactory answer. It is one of the peculiarities of beekeeping, that so frequently it is impossible to accomplish what is desired. Conditions, whether known or unknown, or unnoticed, serve to control events in spite of the most intelligent human intervention.

The foundation of successful beekeeping is a good working knowledge of the natural instincts and ways of the bees, and a logical adaptation of methods so as to harmonize with those instincts, and guide them to our advantage.

The various methods of "building up a colony" have been brought together here in a brief way so as to be available to the reader who may have limited means of information.

The natural increase in a small colony of bees is necessarily slow, even when all conditions are favorable. Consider for a moment that there are household duties to be attended to within the hive which require the constant attendance of a body of bees which is all the time getting smaller. There is the warming, feeding, and capping of the young brood; the feeding of the drones and the queen, housecleaning, propolizing, guarding, etc.; so that, if there is to be any increase in numbers these bees must not only care for and rear others to take their own places, but also many more for the increase.

It is well known that any shortage in the food supply, whatever the reason, immediately curtails the activity of the queen. One of the first requirements, therefore, is to know that there is an ample supply of food in the hive, or, if there is a shortage, to supply it at once—not in one great deluge, which is not nature's way, but steadily and in moderation. Thus we set up a good imitation of natural conditions of food supply.

Feeding is for the purpose of making "times" less "hard," and creating among the bees feelings of hope and confidence which natural circumstances may have prevented. Apply the figure to ourselves, and observe how much better we work, and how much more we accomplish when hope and confidence keep us company.

The natural and very logical habit of keeping the brood-nest as nearly as possible solidly spherical, and the refusal of the queen to deposit eggs much if any beyond those limits, gives us the opportunity to place empty comb space within those limits where the queen can and usually will get busy very promptly—in fact, laying just that many more eggs than she would under the original condition. There is need to be careful, however, that weather conditions be settled and warm; also that the colony shall have bees enough to carry on the added work, or this "spreading of brood" should not be done.

The weakness of a colony is very often due in the first place almost entirely to the queen's failure to produce brood sufficient to keep up the population. This can be determined partly by her appearance and movement, and partly by the proportion of brood to adult bees in the colony. A prolific queen will keep a much larger proportionate amount of brood than will a poor queen. It follows naturally that a new queen will be the proper remedy. A young queen will give the house bees all they can do, and they will, perforce, have to work harder with consequent good results.

Too much house room is just as bad for bees as for humans; a small family in a big house has difficulty in keeping warm, and the empty rooms have a depressing effect. Twenty people in a small room vote a meeting a great success, while the same number in a big room say "there was no enthusiasm, there were so few there." Then, too, the small room gets pretty warm, perhaps, while the big room is too chilly for comfort. Therefore divide the brood-chamber by a padded division-board so as to give the bees an apartment suited to their numbers.

Feeding, spreading brood, and requeening, together with adapting space to bees, constitutes about all that can be done toward building up a single lone colony; but when there are other colonies available there are other means of helping the weakling.

When a man is poor, the best way to overcome the deficit is to get money. Fortunately with bees such a proposition is not so silly, and we can put the idea into practice by taking from a rich colony, which can

afford the donation, a frame of sealed brood (which will impose no additional labor upon the weak colony), and giving it, with the bees which may be on it, to the colony to be helped. Such a frame with bees may be slipped in at one side of the brood-nest (not in the middle), and there will seldom be any disturbance. By carrying this operation to the limit, a full-sized strong colony could be built up in about fifteen minutes; but it must be remembered that each frame of brood taken from any colony means just that much setback to that colony, so that what is gained for the weak colony is lost somewhere else.

A good strong colony with a young queen may be able to give up two frames of brood and bees during the season without noticeably affecting their prosperity. If no surplus is expected from such a colony, then it might furnish ten frames of brood, or more, in a season.

There is another method of building up a weak colony, but which is not to be recommended for general practice; and that is, to exchange stands, a weak colony with a strong one. This operates by the field bees going home to the old stand which has then the weak colony. There is risk in this of starting a fight by which more would be lost than could possibly be made up in any way. The result would be two weak colonies instead of one.

There is another way of dividing the bees of a strong colony with the weak one by setting the weakling on top of the strong one with a queen-excluder between, and after a few days setting the under hive off upon a new stand. This is known as the "Alexander method." This operates by giving the weakling the larger proportion of the adult bees, and the hive upon the new stand has all the brood and the young bees. The large amount of brood continually hatching soon builds up the colony on the new stand. This method requires a knowledge of how and when to do it, which makes it necessary to be posted on Mr. Alexander's directions.

These expedients are possible only where two or more colonies are available. There seems to be a point in the number of population above which things go on amazingly on a high tide of prosperity. On the other hand, when the population falls below that critical point there seems to be a drag to every thing; stores disappear, brood diminishes, and a general atmosphere of discouragement can be noticed when the hive is opened. A weak colony is a pathetic sight to the owner.

As a safe suggestion, the beekeeper

should have a clear idea of just what he is expecting to gain by any particular manipulation, and should look both ways before he takes a step.

There is one bit of advice which is always in order; and that is, acquire the best possible theoretical knowledge of beekeeping by reading—yes, studying—books upon the subject; and if one desires the greatest satisfaction, do not stop with one book but

become familiar with all the best writers. If one cannot compass so much, then by all means make the A B C and X Y Z the textbook and guide. There is this great advantage with this book, that it is a cyclopedia of the art and science of beekeeping. It is not the exponent of one man's theory or practice, but is the cream from all.

Lyndhurst, N. J.

AMOUNT OF SYRUP NEEDED FOR DRAWING OUT FOUNDATION

BY GEORGE T. WHITTEN

As there appears to be no end to the discussion on the subject of stimulative feeding I will add more. It is advantageous in any case where there are bees enough to keep the brood-nest warm enough to hatch all the eggs that are laid, or when artificial heat can be supplied; otherwise, in almost all cases it is a waste of time and good material.

A good queen will lay all the eggs that can be cared for, and many more in case of a weak colony. The queen will continue to expand the brood-nest at any time when weather conditions are favorable; and unless means are provided to keep the hive warm by bees or artificial heat, the eggs simply chill and do not hatch, yet the queen continues her work.

The trouble with most of us is that the colonies get strong enough for good work just too late for the honey-flow. They need protection more during March and April than at any other time of year. My bees that are kept in the house build up very rapidly during February, March, and April.

I have one queen that has laid almost continuously, summer and winter, for nearly three years.

I am quite sure that a strong colony will draw out six frames of foundation half way on one quart of syrup. They will draw them out to a considerable extent after being

transferred, before being fed any thing; they utilize the food taken with them when transferred, and that, with the amount of wax in the foundation that they use for cell-building, will enable them to draw out the cells to that extent.

There is surely no mistake in the statement made by the editor, page 794, Oct. 15, and referred to by J. E. Crane, page 52, Jan. 15. Bees will do that, and even better, in some cases; but after they get the cells drawn to that extent it requires many times that amount to finish. They work the mid-rib out very thin when they first start to build comb when there is not much honey coming in. Later they will vary the thickness in proportion to the amount of stores coming. This I have noted at all times.

I have transferred bees many times in winter on to foundation when I was sure they could get nothing except what was given them, with practically the same results each time.

In my opinion, from experiments in the use of different foods for bees, there is nothing as safe, and that will give as good results, as sugar syrup. When feeding syrup I have no trouble, but have more or less when honey or candy is used. The condition of the colony and the season have much to do with the feeding problem.

Now's the time of year when Grandpa and the bees both peep out of the front door, and wonder when the thaw is coming.

Trapping a Bee-eating Skunk

I was interested in the article on page 22, Jan. 1, by H. R. Boardman, but I was surprised that Mr. Boardman was so long in finding out how much damage skunks do. Some years ago I had four bee-yards, and had each yard fenced with a tight board fence 5 feet 4 inches high, surmounted by two barbed wires. I always kept a box trap at each yard, as the skunks would dig under the fence and then devour the bees by the quart, and sometimes by the gallon, I believe.

The reason I used a box trap is this. When I catch the skunk in a box trap I take the trap (skunk and all) and sink the trap in water until the skunk is drowned. There is no scent whatever.

The best bait I know of is an egg, because other animals will not bother it. For instance, if I bait with fresh fish the chances are two to one there would be a cat in the trap within half an hour after sunset. So by the time Mr. Skunk would get around the trap would be closed.

How many bees can a skunk eat in one night? A few years ago I drove out to one of my outyards about seven miles from home, in November, and there was about three inches of snow. I found a skunk had dug a hole under the fence and had sat in front of one of the hives on the stand so long that the snow was melted. He had scratched a strip of paint off the front of the hive about two inches wide clear across the entrance. I took some steel traps and tracked him about one mile, intending to trap him at his hole; but he went in a crack in the ledge which was several hundred feet long. So there was no chance to catch him there.

Then I went back to the beeyard and set the box

trap near the hole under the fence. The next day I had him. He got into the trap before he got to any hive. When I skinned and dressed him there was a teacupful of undigested bees in his stomach. This was about 36 hours after he ate the bees. He weighed over 11 lbs., and I got over three pints of oil out of him. Of course this was a very large one.

PAUL SCHEURING.

Will Granulated Honey in the Cellar-wintered Bees do any Harm?

I am writing you concerning a condition the seriousness of which is yet undetermined. Our bees are snugly quartered in three large cellars, and are apparently doing well; but at the time of cellaring we found an unusual amount of granulated honey in the hives, and we are at a loss to know whether the bees can or cannot use this granulated honey after the liquefied is gone, and before time to remove them from the cellars. We realize that bees will not winter out on summer stands successfully in Utah on granulated honey, but do not know what results will develop from it in the cellar. Since first beginning to cellar our bees the granulation has been very slight until now, but we feel a little uncertain this time.

The cellar temperature of 45 degrees F. plus the additional warmth of the bee cluster has had a tendency to liquefy slightly the granulation since cellaring; and the granulation is less in strong colonies than in weak ones, and is less in the early flow of honey than in that gathered toward the end of the season.

Beaver City, Utah, Feb. 2.

G. W. GIBSON.

[Granulated honey will do no serious damage to the bees in the cellar. Of course we prefer sealed liquid stores; but in the average cellar there is sufficient moisture so the bees will be able to take care of the granulated honey they have. Should the cellar become very dry, which is not likely, they would not be able to use granulated stores like liquid honey in the comb.]

For winter feeding Mr. J. E. Crane recommends granulated honey in place of candy when regular combs of sealed stores are not available, and Mr. Crane is good authority.—Ed.]

Shipping Queens by Freight to Australia

Last season I tried to get queens through the post from the United States, but they all arrived dead. Recognizing the futility of further attempts by post I arranged to have a dozen baby nuclei sent by freight with a queen in each. They arrived in due course, reaching here just before Christmas, in the heat of our summer. They were packed in well-ventilated boxes measuring about 10 x 9 x 5 inches, and each box contained two combs of honey. They had been very carefully put up, and I do not think any thing further could have been done to ensure success unless it was the addition of a water-bottle.

I am not too keen myself on giving the bees water *en route*, as my experience and that of my sons makes me rather dubious whether it is beneficial or not; but I mentioned it because the editor of GLEANINGS has appeared to advocate it. When I unpacked the bees, two nuclei had died outright. One of these had consumed all its stores, and four others had about half the bees and the queens dead. Of the other six alive, some were pretty weak, and two have since died, leaving four out of a dozen. They are good bees, good honey-getters, and very quiet.

MAJOR SHALLARD.

S. Woodburn, N. S. W., Australia.

Bees Starving with Honey in the Hive

Will you advise me what caused all my bees to die in the hive during present winter, queen and all? They had plenty of stores, and were in a double-walled hive which was also protected by a shed which had a clearance of about 6 inches around the hive, which clearance was covered and stuffed with burlap bags, carpets, etc., so that they certainly could not have frozen. We did not notice them flying these fine sunny days, so we investigated, only to find them all dead. There is no evidence of foul brood.

Would you recommend destroying combs now in the hive before putting in new bees?

Pittsburg, Pa.

WM. MCGALL.

[From our own experience with bees wintered out of doors in chaff hives this year, as well as other reports which are similar to yours, we are led to believe that your colony starved to death with honey all around them. This condition was brought about by the long steady cold stretch of winter weather which we had during the past two months. While there was plenty of stores in the hive, yet the bees were so stiffened by the cold that after they had eaten all the honey within reach they were unable to move over, and, consequently, starved to death.

If you are sure that there is no disease in the combs there is no reason why you should not use them again.—Ed.]

Substitutes for Pollen should be Fed

Why use sweet of any kind in a pollen substitute? Mix it according to my method, page 313, April 15, 1914, and I will guarantee that the bees will do the rest in a proper manner.

I have fed flour for twenty-five years with good results, placing it in the beeyard in shallow boxes, rye, graham, shorts, and bran thoroughly mixed. The bees work it as readily as they would natural pollen or even honey. There is sufficient natural oil or starch in the mixture that the bees have no trouble whatever in loading up quickly. I doubt if the bees use any honey in the manipulation of this substitute or the natural pollen, other than that naturally contained in the blossom producing it, L. L. Langstroth to the contrary. True, it is very sweet to the taste, yet is readily crumbled like pellets of flour.

Union Center, Wis.

ELIAS FOX.

Painting Hives is Economy in the End

I take care of over 250 colonies of bees, and have watched every point in bee culture for years. I began when young, and am now 55 years old. I have read that Dr. Miller does not believe that painting his hives is an act of economy.

I want to say to my bee-brethren that, if they make their own hives, and are not willing to use all the paint necessary to protect the wood, they should paint the inside of the hive first. This will prevent the sides and ends of the hive from taking up the moisture from the bees on the inside, and thus prevent the sides from curling out. I favor painting on both sides with good oil paint. I believe this is economy in the end.

Place to Scratch Matches on the Bellows of a Smoker

I have an improvement on the smoker that is so simple that one might smile, and perhaps feel a little disgusted over it; but after using it a few times that feeling will disappear.

Take a little very thick paint; spread it on the lower right-hand side of the bellows, next to the fire-pot. Cover the lower half, and then fill it with coarse sand. After it is thoroughly dry you will smell every time you scratch a match on it.

Bradentown, Ia.

D. W. ABBOTT.

Boards to Protect the Winter Entrance

I notice by Jan. 15th GLEANINGS that the entrance to those large quadruple winter cases on the cover picture contemplates using a board for a runway to the entrance instead of leaning it up in front. I may say that in this locality, where snow gets quite deep, it seems to be a great advantage to lean the board up in front. It prevents snow blocking the entrance, as the snow slides away from the entrance, and it never packs solid under the board. After the first day it does not seem to annoy the bees to have the board there. I am never the least concerned about the entrance if snow is three or four feet deep, as I know they will be all right so far as the snow is concerned.

Lead Pipes in Honey-tanks

We intend to put some kind of spiral pipe in our extracting-tank next year, so that we can turn on the steam and heat the honey enough to prevent granulation. This would be a convenient way to heat bulk comb just before packing it. Does any one know whether the use of lead pipes would affect the flavor or quality of the honey?

Corpus Christi, Tex.

E. B. AULT.

[We have never used lead pipe in connection with honey. We should be afraid, however, that it would not be safe. Can any of our readers report?—Ed.]

Has Tried Eight Hives in a Case

Dr. Miller, p. 95, Feb. 1, suggests trying quadruple winter cases with hives two deep, eight in a case. I tried this two-story plan one year, with the result that in the spring nearly all of the bees were found to be in the lower hives. Perhaps it would work better if the entrances were turned in different directions.

Valparaiso, Ind.

E. S. MILLER.

In opening a colony of bees to note condition a few days ago I found several combs badly mildewed, especially on the ends toward the back of the hive. Will this condition bring any bad results? or will the bees clean it up later?

Quite a number of combs are white with mildew, and I find nothing after searching the A B C and X Y Z.

Morganton, N. C.

L. E. WEBB

[You need have no fear of the mildew doing any harm. As soon as the weather turns warm enough for the bees to fly every day and to build up they will clean up the combs and use them, and without any bad effect on the bees. Mildew is found very commonly on combs in hives in the spring of the year, especially where they have been wintered in a damp cellar; but the same condition is oftentimes found in outdoor-wintered colonies as well.—Ed.]

My Dream Woman of the Bees

BY GRACE ALLEN

She works and she sings, like her bees with brave wings,

Exultantly eager and free,

Unfolding in beauty like flowers of the sod

That flood with their fragrance the sunshine of God—

This woman I'd like to be.

A lover of trees and birdsongs and bees,

She treads where the poets have trod;

Like Martha she labors, and still like the sweet

And quiet-souled Mary she sits at the Feet,

And listens alone to God.

Nashville, Tenn.

OUR HOMES

Editor

By their fruits ye shall know them.—MATT. 7:20.
There is no other name under heaven.—ACTS 4:12.

Since giving place to the letter from friend Boone on p. 958, Dec. 1, I have received several letters of like tenor, some of them severely censuring church members, ministers, and the Christian religion generally. I cannot give space to these letters, for I try hard to have not only every page of my department but *every line* contain some thought that will benefit some one; and I feel sure no one will be helped by giving space to talk that was common in years past, but which, since the great strides of present Christianity, are now mostly dropped and forgotten. I replied to one brother (who sent me quite a long letter) on a postal card, and quoted our text above, and asked him if he was keeping track of the great work now being done by "Billy Sunday." For fear there are others of our readers who are also not keeping posted I have made some clippings from the *Sunday School Times* of Jan. 24.* Of course the brewers and distillers are fighting Sunday with money unstinted, and every thing else; and it seems they have been telling of the \$48,000 that the city of Scranton, Pa., expended in the Sunday crusade. A business man made an extensive summing-up of *expenses*, and also of *benefits*, and gives the whole in the *Times*, and then asks, "Did it pay?"

Below are a few of the points he makes. I know the figures are staggering; but *while I write* the work is being *more* than duplicated in the great city of Philadelphia.

Superintendent Hopper, of the Lackawanna County Sunday-school Association, reports the county membership increased from 35,000 to 47,000, and the most significant fact of the 12,000 gain in members is that *ninety per cent of them were men*—men who could qualify in organized adult Bible classes.

That Billy Sunday reached men is evidenced by another fact. At the last meeting in the tabernacle for men, Sunday, April 19, at 2 P. M., Mr. Roddeheaver requested that all men who had stopped "hitting the booze" since Mr. Sunday came to the city raise the right hand, and immediately hands "shot up"—men vied with each other in trying to raise their hands higher. How many were there? From where the writer sat, on the steps of the platform, it seemed as if almost every man in that audience of 10,000 men had his hand up. From competent judges it was estimated that no less than 5000, and probably 6000, had become total abstainers. Here was visible evidence, and our hearts still glow at its remembrance. A conservative estimate places the number of total abstainers in this valley as the result

of the Sunday campaign at not less than 10,000 men, saying nothing about the women.

Some people say that the Sunday campaign was a failure. Who says this? Brewers and saloon-keepers. Can we refute their statements? The report of the internal-revenue collector for this district is of value. He reports for the first six months of this calendar year 17,000 gallons less of whisky consumed than in the preceding six months; 25,000 barrels of beer less than for the same period last year, and a corresponding decrease in tobacco.

If the 10,000 booze-quitting men spent an average of \$2.00 per man each week for fifty weeks in the year for intoxicants (we have numerous personal testimonies of booze-bills that range from \$20 to \$150 per month), then for an investment of \$48,000 we have diverted \$1,000,000 per year from the hotel and saloons into honorable and legitimate business channels, and into the churches. You say these figures are too high. *They are not too high.* Well, cut the amount in two; was it worth \$48,000 to divert \$500,000 into legitimate business channels and into the churches?

The other day the writer asked an executive auditor of one of our largest corporations what effect the Sunday campaign had on their employees.

"Our employees have been transformed," he replied. "It was the greatest institute for efficiency that we have ever known. In efficiency the company has gained in one month several times the cost of the tabernacle, and in actual cash from loss of time, leave of absence (intoxication), sickness (dissipation), in any one month an amount equal to the entire cost of the tabernacle."

If you are reading the great city dailies you are probably aware that intemperance, crime, destitution, and suffering are increasing at an alarming rate. In the city of Cleveland, Ohio, they are calling for more policemen (because "hold-ups" are getting so common even in daylight, etc.), and the city replies there isn't any more money to pay for additional police. With wars and increasing intemperance what is the *whole wide world* going to do?

This is not only what they are *going* to do, but *are* doing. They are going to wake up, and listen to God's appointed prophets, and repent, and reform.

Now then! Will these friends (these *few* friends) who ridicule my faith in prayer, make sport of the Bible, call "deacons" and "preachers" hypocrites, etc.? Will these friends give us an account of what *infidelity* has done since the world began, in the way of reform? Are they not in about the same predicament as the friend I have mentioned (who was going to convince me by argument that there was no such thing as a queen in a beehive), when I opened a movable-comb hive and *showed* the queen depositing her eggs?

Our blessed Bible tells us of the time when the dear Savior spoke to the boisterous winds and waves; and at his word, "Peace! be still," "there was a great calm."

* I hope every friend of temperance and righteousness, if he doesn't subscribe for the *Sunday School Times*, will at least send for the issues of Jan. 24 and 31, the latter being the temperance number.

Only those who have been out on the great ocean can fully realize what a stupendous miracle this was. No wonder the disciples "marveled" and said, "What manner of man is this, that even the *winds* and the *seas* obey him?"

Now listen to your old friend when he tries to assure you that the present wars, intemperance, and crime are all subject in like manner to *his* command, and that "there is no other name under heaven" that can quell this boisterous world than that of Christ Jesus, who spoke peace to the troubled seas ages ago. And this is the message that God's appointed "Gideon," Billy Sunday, is bringing, and yet the whole world *marvels* to see this one little man the means of bringing peace and joy into the homes of untold thousands, and of making a great city like Denver, Colorado, "vote dry" in spite of all the trained minions of Satan with their ill-gotten millions.

BILLY SUNDAY, THE ANTI-SALOON LEAGUE, ETC.

To give you a brief glimpse of the great work that is now going on to usher in God's kingdom, I make two clippings—one from the *Sunday School Times* and the other from the *Baltimore Sun*. I verily believe Sunday would end the war if he were given a chance, and if all good people would stand by him, as they seem to be doing now, wherever he goes.

To make a state or a nation dry requires votes. Votes cannot be secured until sentiment is ripe. It is by the creation of dry sentiment that the evangelist renders extraordinary service to his country.

In the recent struggle for prohibition in Ohio, more than five hundred thousand dry votes were secured. Mr. Sunday has conducted many extensive campaigns in that state. And it is perhaps the most thoroughly organized state in the Union from the Anti-saloon League standpoint. Wayne B. Wheeler, Superintendent of the League, recently said:

"Billy Sunday attacks the liquor business in the most aggressive, bold, and defiant manner of any man I have heard in years. Many people are aroused to action only when a speaker hits an evil hard, then jumps on it and literally pulverizes it with argument and invective and impassioned oratory. Billy Sunday makes the people feel that the liquor-traffic is the worst crime of our civilization. Some of them may cool off; but many stick, and they furnish good fighters in the ranks of any organization that is making an effective and aggressive fight against the saloon."

On November 3, 1914, Colorado voted dry by a majority of 11,000. Two years ago the same state voted wet by a majority of 40,000. Chief among the elements that entered into this campaign was doubtless the well-nigh perfect organization of the Anti-saloon League, reaching to every voting district in the state, together with the hearty co-operation of all other anti-liquor agencies.

Then came Billy Sunday, arriving in the state at the psychological moment. In June he conducted a campaign at Colorado Springs, in El Paso County, where the wet majority two years ago was 2700. The dry majority last year was 4000. For six weeks

previous to the election Sunday stirred up Denver. The dry vote there was increased from 11,000 two years ago to 29,000 last year.

"There are little frizzled-top sissies not yet sprouting long dresses who know more about vice than did their great-grandmothers when they were 75 years old.

"The girl who drinks will abandon her virtue. What did Methuselah know about smoking cigarettes?

"If any one ever tells you that you can't be virtuous and enjoy *good health*, I brand him as a low, infamous, black-hearted liar."

SUNDAY'S CONVERTS 1184.

At the morning service 157 publicly acknowledged their faith in Almighty God in answer to Sunday's summons for converts. At the afternoon service Sunday ripped off his collar and tore open his shirt, and with the perspiration dripping from his face and arms he lashed, hounded, quartered, and flayed the thousands of sinning men seated before him until he stood before them triumphantly extending God's blessing as they rushed up to the pulpit for forgiveness. There were 551 converts this afternoon and 476 to-night.

Morning, afternoon, and night services were practically continuous. Thousands were gathered before the tabernacle doors at daylight; thousands remained inside the immense auditorium for the afternoon service, and thousands remained after the afternoon service for the night service. None stayed away on account of the rain.—*Baltimore Sun*, Jan. 18.

PEACE ON EARTH, GOOD WILL TO MEN.

I have been not only praying for, but *expecting*, something like what is outlined below, which I clip from the *Christian Herald* of Jan. 20. May the Holy Spirit go with it.

CONGRESS TAKES UP WORLD-PEACE.

On Jan. 2 Hon. Charles F. Curry, of California, introduced in the House of Representatives the first measure ever placed before an American Congress in the interest of world-peace. It was in the form of a joint resolution which reads as follows:

"JOINT RESOLUTION

"Authorizing and empowering the President to invite all nations to send delegates to a convention to provide for disarmament, for the creation of an international legislature, an international court, an international army and navy police, and for other purposes.

"Resolved by the Senate and House of Representatives in the United States of America in Congress assembled, That the President be, and he is hereby authorized and empowered to invite all nations to send accredited delegates to an international convention to frame a constitution for submission to the nations for ratification, said constitution among other things to provide for an international legislature to enact laws for the government of the intercourse between nations; to provide for an international court to adjudicate the differences between nations; to provide for the disarmament of all nations; to provide for an international army and navy to be used as international police, and when so ordered to enforce the decrees of the international court; to provide that each nation shall be protected in its right to retain and maintain its own form of government, and to exercise exclusive authority over its internal affairs; and to provide further that each nation shall be permitted to maintain an army and navy only sufficiently large to police its own territory."

On January 5 the same resolution was introduced in the Senate by Hon. Robert L. Owen, of Oklahoma.

The resolution has been referred to the Committee on Foreign Affairs and ordered printed. It is the outcome of a widespread agitation of the peace movement and of memorials, circulated by the *Christian Herald*, which have been numerous signed and mailed to members of both Houses and the President within the last few weeks.

"THE MAILED FIST" OR "THE PIERCED HAND."

Our long-time friend from away off in New South Wales, Herbert J. Rumsey, sends us a clipping from the *Sunday Sun* of Dec. 13. This edition of the *Sun* was to be mailed to the soldier "boys at the front," and a Protestant minister prepared the sermon from which I make the following extract:

THE SYMBOL OF THE GOSPEL IS A PIERCED HAND.

The pierced hand is the symbol of the world empire of Jesus. During the last few months we have been made painfully conscious of another symbol of world empire—the mailed fist.

We are looking forward to the time when the peace of God which passeth all understanding will fall on this shot-shattered world, when the daisies will bloom on the battlefields that are now red, when the birds will build their nests in the cannon's mouth. There will come an abolition of militarism, new and better international relations, a purged national life, a splendid extension of the kingdom of righteousness and peace and joy. Do you believe it? Are you not fighting for it? To-morrow Bernhardt's law of might will pass, and the world will learn a new but an old word, "Blessed are the peacemakers." A recent illustrated paper contained the picture of a ruined church smashed by the red anger of the Germans. Underneath were written the words, "The cross is not damaged." There among the dust and ruin and horror of it all was the cross, erect, unbroken, and sublime, which things are a parable. We, like Constantine of old, see the cross outlined above the clouds, and reverently cry, "Hoc signo vinemus"—"By this sign we shall conquer." So, above the smoke of battle rises mystically the sign of a cross. Across Europe's bloodiest field there beckons a pierced hand, and as from afar, yet with a note of present confidence, there sounds a voice of triumph, "I, if I be lifted up, will draw all men unto me."

No one can read the gospels without reaching the conclusion that Jesus anticipated a ministry that should be wider than any Jewish limits. He who is reckoned by some to have been a peasant in an obscure province in a far-off age, who wrote no book, who built no church, who organized no army, who left no court, foresaw a ministry which was to be as wide as the world. As a peasant, Christ died when, as men reckon years, he had scarcely reached his prime.

Not a golden hair was gray
Upon his crucifixion day.

Concerning his death, he said, "I, if I be lifted up, will draw all men unto me." The great sayings of Jesus have stood the test of all criticism, and they tell us that throughout his earthly ministry Christ had the outlook of approaching lordship over all the nations. The teaching of Jesus consistently pointed to the fact that his death and world empire are forever associated. His death was to be the secret of world empire. When the one grew vivid in his thought there rose the vision of the other. And that fact should be thought much of by every man and every woman who is interested in the world empire of Jesus Christ. So far as our present ex-

perience has gone, it must be granted that historic Christianity answers all the ends of true religion. It sweetens life; it creates saints; it inspires missionaries; it brings gifts of peace to dying hours; it lifts men by the energy of its grace to better living. It promotes righteousness, peace, and joy. It strengthens all the anchorages of morality. It brings light amid the shadows of life, and, in the darkest valley, the vision of the eternal God. Wherever the gospel has been preached, men have learned a new pity for human pain, a charity that cares for the helpless, a patience that watches over broken and failing life. The gospel supplies new moral ideals by which to shape life, new forces by which to touch life.

May God hasten the day when the whole wide world shall have so little use for cannon that they may prove a safe nesting-place for the innocent birds.

SAN FRANCISCO AND THE EXPOSITION, ETC.; FROM OUR LONG TIME FRIEND W. A. FRYAL.

My dear Mr. Root:—One of your correspondents living in this state makes a very broad and unwarranted charge against San Francisco, p. 44, that I believe should not go unchallenged. I am a native of that city; and while I must acknowledge that many things are done there that are reprehensible, still it is not altogether the bad place that too many narrow-minded persons are too ready to dub it. Few cities as large, and made up of such a cosmopolitan population as she possesses, are more orderly, and as well-managed, as the City by the Golden Gate. It is a city of culture and refinement, even if there is a large sprinkling of elements that cannot lay claim to such designation. Of course, too often the worst element in a community raises a lot of dust that is disgusting to the better classes; but I find that the latter element is to blame, in the majority of cases, in not correcting such abuses. If they would take more civic pride, and vote as their best interests dictate, there would be a better order of things. I have noticed that in nearly all our big cities, even in this elegant city of Oakland, many people of refinement and culture refrain from going to the polls on election day as they should, and voting for suitable men for office, or supporting wise legislative measures when they come up on either initiative or referendum submissions.

Under the old order of things too often bosses who had their origin (and most times instructions) from some saloon saw that their cohorts were rounded up and voted to carry things for the bosses. In this way most of the office-holders were unworthy men, and many of the measures enacted were what they should not be. But the saloon is "getting on to itself," and it is no longer the factor that it was. And this is a good thing for everybody. I have long held that it should be a criminal offense for a bar-keeper to use his place of business for political purposes. It is a well-known fact that some saloons are worth thousands and thousands of dollars to the owners as rendezvous for a gang of politicians. This should not be. Make it criminal for such goings on. And perhaps, too, it would be well to close such places for a certain period, say a week or more before a general election, and shorter for minor ones. All this applies to places where out-and-out prohibition cannot be brought about. In time I believe men will not want to be seen going into a whisky dispensary, even if they are not prohibited from so doing. I believe, from what I see wherever I go in California, there is far from being the intemperance there used to be. This is brought about by several causes. It must be said to the credit of some of the saloon men that they will not sell strong drink to men who are likely to over-indulge. But the great

majority of such liquor-dispensers are not prone to do this. They are too greedy for the dimes and nickels, and every thing goes with them.

I have long been against the saloon; but I cannot bring myself to forcing them out of business without giving them a chance to save the capital they have put into the business. It savors of the worst kind of robbery to do so. Some plan should be devised to recompense them. It would be perhaps cheaper for the state to do this. After a certain number of years all saloons *must* cease doing business, a reasonable sum to be paid for their fixtures or any leasehold a saloonkeeper may be obligated to hold to. By the giving of ample time, all stocks could be suitably disposed of, and the barkeepers have sufficient opportunity to seek other employment. In this way many of the saloons would virtually close out before the time set.

Here in this state the prohibition measure was lost by the stubbornness of those who initiated the movement. They did the cause much harm. It was not lost because the people are in *favor* of the saloon. It was too drastic, and many of our clergymen were not in favor of the proposition as it was submitted to the voters. It aimed to destroy the grape-growing industry in California—something that the people here take great pride in. I believe that, if the proposition had excluded the wine industry, the measure would have carried. I notice that henceforth the viticulturists of the state are not going to affiliate with the saloon interests. They will let the latter take care of themselves. So, I believe, when the question comes up again it will not cut horizontally. It will make reasonable distinctions between what is temperate and what is intemperate. This is well. There's reason in all things. Get at the sin of the thing—strike it—kill it.

What the temperance folk have to be thankful for (and this is where it can be proved that the voters of the state saw the justice of the proposition), was that, when they voted down a counter-proposition of the saloon people, to prevent any further meddling with the liquor question for *eight years* after any election when the question is voted on. If this had carried it would have been a great victory for the saloons. It was lost, as I firmly believed it should have been, and I so voted. The prohibition matter is now being agitated in our legislature, and it may be submitted to the people in some milder form, and finally be ratified in 1916. Let us trust it will be a rational measure.

Now, Mr. Root, what I was going to call your attention to is the last paragraph of the first column on page 44. Any one who would maliciously give the impression that "it is no uncommon thing to find dead bodies floating in San Francisco Bay" bears false witness against his neighbor, and commits as great a sin as if he were a confirmed rum-guzzler. I have lived in sight of the bay mentioned all my life (over fifty years), and I know it as a fact that such a statement is untrue. That dead bodies are found floating in the bay is *sometimes true*. Some of them were suicides; some fall from off the shipping in the bay; some were fishers along the rocks or cliffs who fell in accidentally, and once in a great while one may have been the victim of foul play. But such victims are found in waters the world over, and possibly elsewhere to a greater extent than about the big city of San Francisco. And it would be the height of uncharitableness to say that a saloon man was responsible for such loss of life.

Do not believe for a moment that San Francisco is a dangerous place to go about in. One is perhaps as safe in moving about the docks on the water-front during the day time in that city as he would be on the best street in any well-ordered city in the world. This I know as a fact, as I have been about the wharfs alone and with friends on numerous occasions.

Then it must be remembered that, if the prohibition measure was lost, there was carried a law which will make the tenderloin portion of the city better than ever before. It is the measure known as "the red-light law." Some of the worst elements of the city tried hard to defeat this measure; but it carried, nevertheless. So, also, has the "blue-sky law," which is a good thing too. This will prevent rogues from fattening on the unsuspecting possessor of ready cash.

It must be remembered that at the general election on the 3d of last November women exercised their voting privilege as it was probably never exercised in any part of the United States before, and I am glad to know that our women did better than I had hopes of their doing; for on several minor occasions previously I thought they might have done better on some local matters that they had a "try at." So, on the whole, the out-and-out temperance people should be satisfied with the result when such good judgments of the subject helped defeat the measure.

Did you hear of one of the sad features about the last prohibition fight in this state. It may be said to be only an incident, but the opposition will make the most of it. Mrs. Bidwell, the widow of a gentleman who in his day was a strong worker in the cause of temperance, and who was, I believe, at one time candidate for President on the Prohibition ticket, hired a minister of one of the denominations (he was highly recommended, and was in a measure an able man) to canvass the state as far as he was capable in the cause of the prohibition measure. He was not long "on the stump" when his ways were not very edifying. I believe the League wanted to call him down, but it was powerless, as he was hired by private means. Any way, this savory minister had a family somewhere back east; but, aside from this, he had an "affinity" here—the wife of a worthy man in one of the northern counties. Well, this alleged laborer in the Lord's vineyard boldly went about through the country preaching against the liquor traffic while he was openly living an adulterous life. Fine example! Of course I would not hold the temperance people responsible for such doings; neither it is any reflection on the church for having such black sheep. And how often things go wrong with the church, and the wicked escape! When the great fire swept over San Francisco in 1906, every church in its wake was completely wiped out, and some of them were very fine edifices; and yet something like six saloons in the burnt district escaped unscathed! It was very strange. I saw some of these places a few days after the fire, and wondered how they were saved. The fire seemed to leave them alone. One of the biggest wholesale wine places was in one of the best blocks that was saved. It was not that the liquor men had influence in having them spared—they (the saloons) were avoided(?) by the Fire King. In a few places I was told wine was freely used to quench the blaze. I presume whisky would not do, as it would add to the fury of the fire.

But the saloon business, as I have said before, is not as bad here as it formerly was. Dozens and dozens of saloons have had to close up, as there was not sufficient patronage to support them. I don't think it is altogether on account of the hard times. It seems to be more because the drink habit is not as popular as formerly. Few men nowadays feel free to ask a friend to come on and take a drink with them. It was that social part of the matter that brought so many into the barrooms.

It is a matter of only a few years that the drink habit will die out. In the mean time, perhaps, with Christianlike prohibitive laws, the nefarious saloon will pass away. But drastic prohibitive measures which confiscate a man's life-long earnings I believe to be against God's laws. Lead the bar-keeper away from his bar. Let him see the evil he too often does.

I trust you will not do as your fair correspondent

would have you do—keep away from San Francisco and the big fair for the reason she sets forth. You will miss a big treat if you do. Come by all means during the year and see the fair. And if you come, be sure to visit me—better, be my guest during your visit. Mrs. Pryal and myself would be glad to have you and yours visit us. We have plenty of room in our fine new home, and we think we can make it pleasant for you. And it will give me pleasure to show you about, as we have a touring car and can get around in a very satisfactory manner. It was my pleasure, some sixteen years ago, to drive Mr.

and Mrs. Thos. Wm. Cowan about this city and suburbs to see the sights. Let it be mine, too, to show you about this beautiful country.
Oakland, Cal., Jan. 11. W. A. PRYAL.

Many thanks, my good friend P., for the facts given us, and also for your very kind invitation; but Mrs. Root and I are getting rather old to take in expositions as we once did.

HEALTH NOTES

CANCER—CAN IT BE CURED BY DIETING, ETC.?

The following is from a friend whose wife died of malignant cancer, and who himself was beyond the reach of treatment ordinarily given by our best physicians. The letter, as you will notice, was written five years after he began dieting, daily bathing, exercising, etc. As you will see, there has been considerable criticism of T. B. Terry's claims, and I am glad to see him vindicated. And I am also glad of the valuable hints given, especially since they come from one who has been for long years a successful practicing physician.

"ALONE WITH GOD."

You may remember my writing to you shortly after your publication of a letter in your department of GLEANINGS from a "friend" whose name was withheld, who had treated successfully a lady afflicted with cancer of the breast without surgery or drugs. I asked his name and address. I was not surprised when you referred me to Mr. Terry. You also mentioned that you had been severely criticised for the publication of that letter. Now, Bro. Root, I am of the opinion that your critics should be criticised, for you did the right thing in allowing that letter a place in your magazine. I for one am extremely thankful to you for publishing it. Had it not been for that letter, I myself might have been numbered with those who have succumbed to cancer. I wrote to Mr. Terry, and he gave me his opinion, and some special advice. I was a tea and coffee drinker, a "tea drunkard," using about a pound of tea each month. Well, I went to doctoring myself with medicines, ointments, etc., and at the end of a year I was no better but much worse in every way. I had grown so desperate in my failure to find relief that I was ready for a surgical operation, but hesitated to use the knife. Then I made arrangements to go to a cancer specialist who used a killing plaster in taking them out. I still felt in doubt. I was "alone with God," and I had been much of the time since my companion was taken. I took the matter up with him most earnestly, and finally decided to get back to nature, and give her a chance. That was five years ago this month. I abandoned tea and coffee and all stimulants, pork, and all rich greasy foods, getting right down to the Terry diet as nearly as possible, only two meals a day. I had been eating three meals before, giving up medicines of all kinds, and, later on, sugar and salt in or on my food, using a little honey, and a little milk and cream. By the middle of July I had lost 30 lbs. of flesh, and was so weak I could with difficulty get about home with a cane.

I had taken up with the dieting a thorough course of hydropathic treatment, daily baths, internal and external, with hot fomentations for half an hour or longer over the cancerous places. This water treatment I kept up for a whole year, not missing a day.

By the middle of September I began to feel I was gaining. I was not so nervous, but more cheerful. My cancers were not so troublesome and sensitive. Well, to make a long story short I will say my cancers gradually were absorbed and disappeared, so there is at present no sign of them left—only a little sensitiveness sometimes over the places. My piles also disappeared by magic, and give no trouble. I am full of hope and life, like a boy, though perhaps more serious, for I am constantly "alone with God." So now, Bro. Root, don't blame yourself for having been so foolish, as some thought you were, for publishing Mr. Terry's letter.

I am "alone with God," Bro. Root, in other ways than material distance from many of my fellow beings. I'm separated from them in thought and habits of life. I cannot go over to them, to my old thoughts and habits of living, and they are slow in accepting my ideas or ways of doing. For instance, I called on a neighbor and found him sick in bed with a cold. He had been taking calomel and other "doctor's stuff." He asked me what I "took" when I got a cold. His idea was on medicines of some kind that would chase the "cold" out of the body, as you would chase the chickens or pigs out of your garden. I told him, "I take a fast, an injection, a good bath, go to bed, and let nature do the rest." That plan did not suit his ideas. I seldom go out to dine with a neighbor, for I cannot go back to my old dietary habits without danger of recurrence of some or all of my old ailments. If any thing is offered me to eat it is almost sure to contain salt in excess, and hogs' fat, both of which are bad for me. I'm urged to have a cup of coffee. "It don't hurt you." So I'm very much "alone with God" and his hand-maiden Nature.

Alone with God when I am weak;
Alone with God—his strength I seek;
Alone with God—for him I long—
Alone with God—he makes me strong.

Alone with God, I flee for rest;
Alone with God when evil pressed;
Alone with God I love to be;
Alone with God—he comforts me.

Alone with God, I struggle on;
Alone with God to gain my crown;
Alone with God—he takes my hand;
Alone with God to heavenly land.

Alone with God, no human near;
Alone with God, no one to fear;
Alone with God I love to be;
Alone with God—he comforts me.

Mentone, Ala.

DR. C. F. PARKER.

HABIT-FORMING DRUGS, ETC.

In the Jacksonville *Times-Union* for Oct. 13, 1914, a full-page illustration is given to the matter of habit-forming drugs. Below is a clipping from the article, together with the lengthy heading:

AMERICAN DRUG FIENDS OUTNUMBER CHINESE; ONE PERSON IN UNITED STATES OUT OF EVERY 23 USES SOME OPIATE. INVESTIGATORS FOR MRS. W. K. VANDERBILT, SR., DISCOVER.

The greatest drug-using people in the world are the American people, and not the Chinese. That is the discovery of experts working under the direction of Mrs. W. K. Vanderbilt, Sr., who, since January, has been working against the use of drugs in the United States.

To-day 4.1 per cent of the Chinese are drug-users in some form. In America, 4.45 per cent of the population use drugs.

Mrs. Vanderbilt began her fight on the nationwide use of drugs in the New York legislature, where she fought for a bill prohibiting the sale of cocaine, heroin, and morphine. She has given large sums of money to organizations opposing the drug habit in her efforts to obtain legislation against its sale.

The entire civilized world has been shouting about the horrors of the opium traffic of China. The Chinese were the originators of opium, it is believed. In China it was found 200 years ago that 6 per cent of the people were drug victims. By consistent fighting against the use of drugs; by laws limiting its manufacture and sale, the use of drugs there has dropped to 4.1 per cent of the population in 200 years.

In America, however, the use of the drug is on the increase.

Laws preventing the transportation of cocaine from one state to another are sought by Mrs. Vanderbilt; and in working for federal laws her experts have compiled data to show the enormity of the drug habit.

Drugs are used by all classes. The criminal class is addicted to its use. Cocaine is injected into the arm. Opium is smoked and taken in other ways. Sometimes the drugs are snuffed. They are taken to drive away the feeling of drowsiness sometimes. Country doctors acquire the drug habit because of their long hours of work. They take drugs to keep themselves awake, and take other drugs so they can go to sleep quickly.

Society women are known to take drugs to drive away weariness in pursuing their social conquests.

In America, drug-users quickly take to cocaine and heroin. The drug causes the user to turn criminal and to die. Five years is the average life of the cocaine fiend.

No other vice renders its victim so dangerous. Opium, morphine, and hasheesh send their victims searching for solitude; but a sniff of cocaine, after lifting its victim into a half hour's rosy overestimation, drops him into the streets and alleys in a state of dangerous melancholia. So brief is the drug's effect that it takes from \$4 to \$5 a day to satisfy a cocaine addict.

"Cocaine addiction is the easiest habit to acquire and the hardest to cure," says Dr. Podstata, a Chicago drug expert. "Nothing so quickly deteriorates its victim or provides so short a cut to the insane-asylum," says Dr. Towns. Because it takes such a quick, deadly grip on its victim, there are some physicians who refuse to administer any cocaine whatever, even for legitimate medical practice.

May the Lord be praised for one more woman of wealth who uses her wealth and influence to protect and reclaim, if possible,

the "dope fiend." With the world-wide stir now going on in regard to the matter, I think these dangerous agents will very soon be under strict surveillance. One reason for the statement above is that, while we are having a mighty reform over in China, America has to a considerable extent been getting worse and worse. May God help us.

But what argument in favor of the American saloon, so far as "personal liberty" is concerned, will not apply to the "personal liberty" of the unfortunate wretches described above?

URINARY TROUBLES, GALLSTONES, ETC.

When I ventured to give an opinion in regard to this matter on page 832 of our Oct. 15th issue I knew I was getting off from my beat; and you may recall that I said I should be glad to have some regular physician straighten us out. A good doctor from away off in northern Michigan has very kindly answered this invitation, and gives us the following:

Mr. A. I. Root:—In your Health Notes in GLEANINGS for Oct. 15 you discuss urinary troubles and gallstones; and the conclusion to be drawn from your article is that the sediment of retained urine causes gallstones. Kindly allow me to correct you as well as your correspondent. Gallstones form in the gall-bladder—a small sac that hangs just under the liver, and which is really a reservoir for surplus bile which is formed in the liver. This gall-bladder has a duct which empties this bile or "gall" into the duodenum, and it is down this duct that gallstones pass and cause all their trouble. This duodenum is the first division of the small intestine, and so you see the gallstones can have no relation whatever to the kidneys, urethra, or bladder. Now I will tell you and your correspondent just what the trouble is, and why it is best to empty the bladder at night if the inclination comes.

Urine, when fresh, is acid in reaction, and in this acid condition it will not decay; but on standing it will soon become alkaline, and then will decompose. In older people it often becomes alkaline before leaving the bladder, due to the inability to expel all of the urine.* This retained urine is called "residue urine," and this will soon decompose, causing an irritation of the bladder, and the bladder must be emptied to obtain relief. Now, don't you suppose that your experience of eating acid fruits has had a tendency to keep the urine acid longer, and thus allow it to be retained? A good many cases of so-called "gravel" in the bladder are simply cases of retained residue, alkaline and decomposed.

Hart, Mich., Oct. 19. L. P. MUNGER, M. D.

* If the readers of GLEANINGS will excuse me (especially the younger ones) I wish to repeat something that our good friend Terry said some time ago. It is rather plain talk for a home journal, I admit; but in view of the importance, especially to elderly people, I think best to give it. The part I recall is something like this. In speaking of the troubles we have been discussing, our good friend remarked that those afflicted in this way should take plenty of time to get rid of "the very last drop" of urine remaining in the bladder. This would tend to prevent what the good doctor in the above calls "residue urine."

Gleanings in Bee Culture

Gleanings in Bee Cul-
ture, one year . \$1.00

One Three-piece Quality
Kitchen Set No. 507, \$1.00

Combination
Rate . . \$1.50

The Three-piece Quality Kitchen Set is made up of three of the most useful kitchen accessories it is possible to combine, viz., an EIGHT-INCH SLICING-KNIFE, a SEVEN-INCH KITCHEN SPATULA, and a STRONG TWO-TINED FORK. The steel used in the blades is the best obtainable, and is finely tempered. The blade of the slicing-knife is full swedged, and the edge stone-ground under water. The spatula and slicing-knife are both finely etched and very highly polished.

The handles of all three are of genuine cocobolo with beveled edges. They have through tangs with three large brass saw rivets. The set is all the name implies, QUALITY, in the strictest sense of the word. We guarantee satisfaction.

GLEANINGS IN BEE CULTURE, one year, with a QUALITY Kitchen Set No. 507, \$1.50.

The A. I. Root Company, Medina, Ohio

Canadian postage 30 cts. extra. Foreign postage 60 cts. extra.

EDITORIALS

Edition of Iowa Report Exhausted

MR. PELLETT has just advised us that the third annual report of the Iowa bee-inspector has met with such a large demand that the supply is now practically exhausted, although it has been out only about six weeks. A few copies only are left for use in libraries. The demand continues large for all of the publications. Some of the bulletins are already nearly gone, so that revised editions will be necessary.

One More Ghost Laid

ANTONIO R. MALAQUINA, of Salto, Uruguay, reports that he has won his suit with proprietors of vineyards at Salto, who were seeking damages on the ground that his bees puncture and destroy the grapes. A year ago several vineyard owners located near his apiary notified him to move his bees, on the charge that they were a nuisance. When he failed to do so they sued him, but he reports that he was able to win the suit entirely without counsel.

Señor Malaquina wrote to GLEANINGS for a statement of evidence and precedents which he might use in his case. Through some error in translation the editor of GLEANINGS was made to say that the bees do ten times as much harm as good. This naturally surprised the beekeeper, but he was able to win his suit notwithstanding.

More about the Swamp Bees

GEORGE H. REA just returned from the Dismal Swamp apiaries and reports that the bees are gathering a little honey and pollen, and brood-rearing is progressing in a very satisfactory manner. While a blizzard was raging in the North the sun was shining there every day (first week in March), and the bees worked right along. The temperature during the daytime was around 60 to 70 degrees. While there was frost one or two nights, it was not cold enough to give brood-rearing a setback. The residents of that section do not expect

many more frosts. The fact that thousands of bushels of early potatoes and acres and acres of garden are in process of planting is evidence of their faith in the advent of continued warm weather.

Oklahoma Foul-brood Bill Passes both House and Senate

N. FRED GARDINER, of Geary, Okla., has just informed us that the new foul-brood bill has passed both branches of the legislature by the following vote: House, 70 to 10; Senate, 29 to 5. The bill is now in the hands of the Governor, and his signature is expected.

Oklahoma has long needed a good foul-brood law. Two years ago a similar bill was introduced into the legislature but failed to pass. It is to be hoped that the beekeepers who have worked so hard to secure such a law may now be rewarded.

How the Bees are Wintering

It is still too early to say definitely how bees in northern localities have wintered. Reports so far are conflicting, although it is probable that there is considerable loss in localities where the bees last fall gathered considerable aster honey, especially where there was a long period of three months or more when the bees could not fly. There are many reports of excessive spotting of the hives.

On account of the fact that in most localities snow covered the ground during the coldest part of the winter, clover looks very promising.

Our Cover Picture

THE cover design gives a view of the Jupiter dock and the Government buildings in the background where the wireless messages are received, as referred to by E. R. R. in his article in this issue, page 225. Our cruiser is shown in the foreground, moored

to the dock. It was at this point where Harry DuBois met us, and from which our party went up the Loxahatchie River to inspect his beeyards.

Perhaps some of our readers will wish to know what that cruiser cost. Somewhere about \$5000. It is constructed to stand heavy seas; is furnished with full equipments in the cabins for sleeping, eating, and cooking. Cruising is the most enjoyable way of seeing the country in Florida that I know of. In this particular case we did not buy the cruiser, but chartered it for a couple of weeks.

The Parable of the Barren Apple-tree

WITH all that has been said at fruit-growers' conventions and written in fruit-growers' magazines, it is hoped that the horticulturists this year will recognize more fully the indissoluble connection between their interests and those of the beekeepers. Since the winter has not been so severe as to kill off great numbers of colonies, the outlook is favorable for the pollination of fruit-blossoms. From that, it follows a good fruit year is due.

In this connection a specific example reported by Dr. B. N. Gates, at the Iowa State Beekeepers' convention last November, is of exceedingly timely interest: "In one of the western states there are two comparable apple orchards of about equal acreage, of similar location and age, each in a pocket in the foothills of an admirable fruit land, both well drained, and protected from frost. One orchard bore heavily for successive years. On the other there was no crop, although the trees blossomed heavily each spring. In despair of financial ruin, the owner called the assistance of the State Experiment Station. A pomologist and entomologist was sent to examine critically all of the conditions at each of the orchards. He was about to return without solving the problem of failure, when the question arose, 'Were there ever any bees maintained in the orchard which had fruited?' It was asserted, however, that neither orchard had bees. However, the problem was not given up, and the ground was again gone over. As the experiment station man was about to leave without finding any apparent reason for failure he chanced to see a stream of bees coming in one of the orchards from a swale under a pile of underbrush. Further investigation revealed a hollow log sunken in the soil sheltering a large colony of bees. It is needless to say in which orchard the log was. Immediately

bees were secured for the failing orchard. The owner then netted \$3800 on his crop."

Have we Really been Testing Queens?

In *Science* for February 5, Wilmon Newell, state entomologist for Texas, who has been studying inheritance in the honey-bee, has announced a few interesting observations which have been brought out by four years of research. At an isolated station along the Gulf Coast, crosses between pure Carniolans and pure Italian stock are being observed.

Mr. Newell finds that the workers of typical Italian color, produced by an Italian queen, are not evidence that she has been purely mated, although this has long been the assumption of queen-breeders. Italian queens mated with Carniolan drones produce workers and queens often indistinguishable from Italians so far as color is concerned. When Carniolan queens are mated to Italian drones the yellow color is also predominant. He has not experimented with blacks.

Offspring of the first of these crosses show a proclivity of the Carniolans for using wax instead of propolis. Bees from the second show it also, but in less degree.

Daughters of these two crosses each produce drones of both races in equal numbers, but produce no hybrid drones. "The actual application of this is that the only test of an Italian queen mated is found in the color of the drones produced by her daughters."

This statement of Mr. Newell's is somewhat tempered by the consideration that when more data are secured on the wide variation in color of drones from purely mated queens, more light will be thrown on several phases of the problem. At best it is rather discouraging to queen-breeders to learn that the only way to discover whether a queen has been properly mated is to examine her grandsons.

Sugar Consumed in the United States

FROM the Bureau of Foreign and Domestic Commerce of the Department of Commerce at Washington we learn that in twenty-five years the sugar consumption of the country has almost trebled, and has increased from 50.44 pounds per capita, in 1889, to 86.85 pounds in 1914. In that period of twenty-five years Cuba has increased its contribution to the domestic market from 1,032,000,000 to 4,927,000,000

pounds, and the non-contiguous territories of Hawaii, Philippines, and Porto Rico have increased their shipments of sugar into continental United States from 511,000,000 to 1,873,000,000 pounds. Europe, the Dutch East Indies, and other foreign countries, on the other hand, have decreased their sales to this country during that same period from 1,219,000,000 pounds to 23.4 million pounds in 1914. The domestic product has grown from 349,000,000 to 1,841,000,000 pounds. Our exports of sugar have increased from 20,000,000 in 1889 to 97,000,000 pounds in the year ended June 30, 1914, and in the three months ended with Oct. 31 there was the enormous export of 230,000,000 pounds; in round numbers, more exactly as follows: August, 38,956,305; September, 52,290,773; October, 138,372,686, or a total of 229,619,764 pounds.

In the fiscal year of 1913 only 44,000,000 pounds was exported. In 1910, 125,000,000 pounds.

The following table shows the leading factors in the sugar consumption of the United States and its relation to the world product in 1894 and 1914.

FACTORS IN SUGAR SUPPLY AND CONSUMPTION.

	Millions of Pounds	
	1894	1914
Domestic product		
Cane sugar	610.8	601.1
Beet sugar	44.7	1,240.0
Total	655.5	1,841.1
Cane sugar from:		
Porto Rico	75.5	641.3
Hawaii	326.6	1,114.7
Philippines	124.1	116.7
Total U. S. islands	526.2	1,872.7
Cuba	2,127.5	4,926.6
Other foreign countries	1,181.2	21.0
Beet sugar from foreign countries:		
	510.4	2.4
Total from foreign countries	3,819.1	4,950.0
Sugar exports (including shipments to U. S. islands)	64.3	96.8
Domestic sugar consumption	4,936.5	8,567.0
World's sugar product	16,532.3	35,860.0
Percentage of domestic-sugar consumption supplied by:		
Continental United States	13.3	20.6
U. S. islands	10.7	21.9
Cuba	43.1	57.5
Other foreign countries	32.9	0.2

Another Admonition against Arsenate

Is it too soon to begin this year's series of warnings to ignorant and thoughtless fruitgrowers against spraying during bloom? Doubtless in 1915, just as in every other year, the reckless will add to the untold damage which has been caused by spraying with lead arsenate while the blossoms are yet on the trees, although it is to be hoped that, with all which has been said and written on this subject, some diminution in this inconsiderate carelessness will be noticed.

"Never spray any fruit-tree while in

bloom" is the caution of the Connecticut Experimental Station Bulletin No. 184. "It kills your best friends, the honeybees, which pollinate the flowers and help to increase the yield of fruit. The spray will also injure the delicate floral organs, so that fruit will not set." In giving directions for the control of the canker worms, bud-moths, tent-caterpillars, and brown-tail moths, which feed upon the unfolding leaves, the bulletin says to spray *before the blossom-cup opens*, though not until the surface of the leaves has expanded sufficiently to hold the poison.

Fruitgrowers who do not understand the relation between bees and fruitgrowing (and, unfortunately, there are still such men) will be persuaded to stop this practice probably only when they realize that filling the blossom-cup with poison is not only not necessary but positively an injury to the delicate organs of the flower, and a handicap to the future growth of the fruit if it manages to survive. Best results will be secured by pounding this truth home quite as forcibly as the fact that bees are necessary for perfect pollination.

The Pennsylvania Meeting

THE Pennsylvania beekeepers met in their eleventh annual convention in the Senate Caucus Room of the State Capitol at Harrisburg, on Tuesday evening, February 23, holding also two sessions on Wednesday, the 24th. This proved one of the most enthusiastic and probably most important meeting of the association. While the attendance was not as large as at some former meetings, yet the keen interest shown in bringing Pennsylvania to the front was remarkable.

Reports by members and inspectors showed that last season was not up to the average, and that foul brood was extremely bad.

It was brought out that the Pennsylvania association has the second largest membership in the United States, and is second only to New York in honey production. It is also the second largest apple-producing state in the Union. The crop for 1914 was 23,100,000 bushels. Because of their importance to the fruitgrower in the pollination of fruit bloom it is of prime importance to save the bees from the ravages of foul brood.

With two or three exceptions the program was carried out as advertised. The various papers and talks aroused lively discussion and developed some important steps.

One member introduced a resolution boosting Prof. H. A. Surface for State Secretary of Agriculture, which was unanimously adopted, signed by every member present, and later submitted to the Governor by a committee. The Governor received the committee kindly, and showed much interest in the needs of the industry. After careful consideration he did the unusual and unexpected for one in his position by suggesting to the committee that an independent bill be introduced asking for an appropriation of \$50,000 for bee inspection. This suggestion was acted upon, and the bill is now in the hands of the Agricultural Committee of the House. If passed it will supersede the item for that purpose now in the Agricultural Budget. The bill has the endorsement of Secretary Critchfield and the hearty support of several members of the House and Senate who were interviewed.

If the Pennsylvania beekeepers and fruit-growers will write their representatives at once, asking them to support the bill, it will stand good chances of passing. With such an appropriation the state can be systematically covered by inspectors, and all bee-diseases brought under control. The beekeepers themselves, moreover, can be educated to better methods. It means millions of dollars to the citizens of Pennsylvania.

We hope to have a picture of the convention in the next issue.

Bees and Orange Culture

A NUMBER of monographs have been published of late upon the relation of bees to horticulture. These articles and pamphlets upon the general subject of the service of bees in pollinizing fruit-blossoms have been increasing the interest of fruit-men in the honeybees and the realization of both horticulturists and apiarists that nature has indissolubly linked together their interests. It has remained for E. G. Baldwin, A. M., of DeLand, Fla., to discuss the bearing of this new science upon citrus fruits in an article entitled "Honeybees in Orange-groves," written for the *DeLand News*. Professor Baldwin, a member of the faculty of the John B. Stetson University, is a practical beekeeper as well as a close student of botany and entomology.

Everybody knows, who has had even the most elementary instruction in botany, that fertilization of a blossom takes place when pollen from the stamen reaches the embryonic seed through the pistil. In some flowers the process by which this takes place is quite as simple as the foregoing statement

of the principle; but in far the greater number fertilization is a complex process, requiring the services of one of two outside agents—either the wind or insects.

In those plants such as some varieties of the strawberry, in which stamens and pistils are borne on different plants, the pollen must be carried a considerable distance in order that fertilization and development of the fruit may be assured. In Indian corn the pollen from the tassel must fall upon each strand of silk for every grain to be developed. Maize is best produced in countries where the sweep of the wind is almost uninterrupted.

In the orange-blossom the pollen must be carried from the stamen up to the pistil. To rely upon the wind alone for this service would be about as uncertain as the breezes themselves, so that in places where calms or damp weather are frequent the agency of insects is extremely important in the fertilization of these blossoms.

Here is where the nectar secreted by orange-blossoms is valuable. This thin watery fluid to be found in almost all plants, every beekeeper knows is the base from which the bees make their honey, but beyond this it has no other intrinsic use. Nectar is simply a bait to lure the bees, get them to brush against the stamens and the pistils, and thus unconsciously perform the service which the wind only partially accomplishes, but which is so essential to the production of fruit.

Damp weather hinders the work of all the insects but the honey and bumble bees. In Florida bumbles are scarce. Upon the honeybees, then, depends the success of Florida orange culture.

Of the growing popularity of bees among orange-growers, let Professor Baldwin speak directly: "In some parts of Florida, the citrus-growers are recognizing their need of something more dependable than mere chance to fertilize their groves. Formerly the beemen were too few, or had too few bees in proportion to the number of groves, and there was an antipathy to bees on the part of many, because they thought the bees damaged the trees, blossoms, or fruit, by their coming and going to and fro. As a result, heretofore, beemen have had to pay a rental for the privilege of putting their bees in groves, locating an apiary inside an orange-grove, for instance. But enlightenment is coming. Now the fruit-men actually court the presence of the bees. Notably around Bradentown, the citrus-men actually offer the beemen free rent for beeyard sites, and in many instances even buy bees of their own to place among the trees. It is worth

noting also that the Manatee Fruit Co., of Palmetto, has established three beeyards in or near their groves, and still wish more. They declare that, the nearer the bees are to their groves, the more fruit they have, and the better the quality. . . . For not only does cross-fertilization increase the amount of fruit, but it also betters the quality, encouraging a heartier growth and development wherever the pollen of one tree is mixed with the blossoms on another tree—just as, for example, a mixture of races produces the hardiest types of mankind.”

Not less than five colonies to an acre are necessary for best results, says the writer, but more are better.

Professor Baldwin's discussion is elementary, but written not so much to convince the layman as to relieve the lamentable lack of information among the growers of citrus fruits.

=====

The National Convention at Denver ; All is Well that Ends Well

SINCE our last report of the proceedings of the National convention there developed toward the last a “little flurry” that promised at one time to develop into something serious; but no sooner had it started than a movement toward peace was under way. The differences and misunderstandings were speedily adjusted. All is well that ends well, and so in this case. We believe the National Beekeepers' Association has a bright future before it. The “bone of contention” for the last two or three years has been over the official organ, the *Beekeepers' Review*, the manner of receiving and disbursing the funds, and the “debt” that has been staring some of the members in the face. No one has questioned the absolute integrity of any of the officials, who have worked faithfully and hard for the best interests of the organization for little or no compensation. A resolution was unanimously adopted, tendering the thanks of the delegates for the faithful and conscientious service of Mr. E. D. Townsend in the conduct of the *Review*; and those of us who have ever had any thing to do with the running of a bee-journal know what that means.

The real question at issue was over the wisdom or policy of handicapping the National by loading on to it the burden and financial responsibility of an official organ and the additional burden of business and finance.

As stated in our last issue, the whole matter was most amicably adjusted by making the function of the National Beekeepers' Association purely educational and

social, with no legal connection with any bee-paper or any matters of business. An auxiliary organization duly incorporated with sufficient capital stock to do business is expected to take over the *Beekeepers' Review*, assume its indebtedness, continue its publication, and transact any matters of business its stockholders may elect. It is expected, also, that the two organizations will be very closely allied, although legally entirely separate. The *Review*, to all intents and purposes, will be the official organ of the old National; but the latter, as explained, will have no financial responsibility for its management.

This, in brief, is the solution of a problem that has sorely vexed the delegates for the last two years. Whether the auxiliary succeeds or not, the result will in no way involve the success of the old National Beekeepers' Association (formerly the North American Beekeepers' Association) that has been in existence for over forty years, and which has been such a power for good. With the “bone of contention” removed, and with no legal or financial responsibility, there is no reason why it cannot be, in the future what it has been in the past.

The success of the auxiliary or business organization will depend on how well beekeepers subscribe for its stock and the kind of business manager they select. The Colorado Honey-producers' Association has succeeded because the beekeepers of Colorado organized a stock company, subscribed for the stock, and selected a business manager, who, in the language of the day, has “made good.” If the proposed auxiliary “makes good” it will be largely because of its manager. Many a time a capital has been dissipated by a poor manager, or because the directors failed to support the policies of a good manager.

CONVENTION ECHOES.

Many valuable papers and addresses were given at this convention—perhaps more than were ever given at any previous meeting of the Association. As these will doubtless be given in full in the *Review*, no attempt will be made here to give even a digest of the general papers. As our space is limited we will attempt to cover very briefly those discussions that relate to policies of the National.

INCREASING THE DEMAND FOR HONEY.

The deplorable condition of the extracted-honey market at the present time, as an indirect result of the Great War, received its fair share of attention. Dr. Phillips, of the Department of Agriculture, made the statement, in this connection, that the Government reports showed that as much honey

is now being imported into this country from foreign countries *in a single month* as was formerly imported before the war *in a single year*. When it is considered that South America and the West Indies produce vast quantities of honey, and that the great bulk of it that has hitherto gone to Europe now comes to this country, it will be understood why the price of extracted honey is so low. Of course, the influx of the imported article does not account for *all* of this reduction. Something must be charged up to the general trade conditions as a result of the war.

The members of the convention were by no means unanimous as to the best way to meet this condition. Secretary Williams believed that the National should encourage its members to do local advertising. He mentioned in that connection the value of display advertising-cards which the National could furnish very cheaply to beekeepers; of live-bee demonstrations; of form letters; of articles in the local press calling attention to the use of honey as a food. Such measures would involve but little expense, and yet if all would thus attempt to boost their markets the sale of honey might be enormously increased. In the line of *general* advertising, he suggested that the National raise a fund that could be used for the purpose by getting the beekeepers of the land to submit to a voluntary tax based on so many colonies or so many pounds of honey. If this plan were properly worked, a large sum might be made available for increasing the demand for honey. Some general discussion followed, but no definite plans have been formulated as yet.

NATIONAL PROBLEMS.

On this subject Prof. Francis Jager delivered an address that was listened to with the most careful attention. By the way, he has charge of the apicultural school at the University of Minnesota, Minneapolis, and according to Vice-president Pellett he is making a great success of it. He certainly made a most favorable impression on this convention.

In his address Mr. Jager called attention to the evident errors and inequalities in the United States Census for 1910. For example, Colorado is credited in that report with producing only 4 lbs. per colony, while Minnesota produces $4\frac{1}{2}$ lbs. In the census there are more jackasses than beehives. Many beehives must have been missed. On the whole, our industry seemed to be on the decline when the reverse is true. No account is taken of bees in cities and towns. Why was this? The Government has supported "infant industries" such as the trusts

and the Union Pacific. These babies have now grown large. Our industry is an infant industry. It needs more help. The sum of twenty-five million dollars is annually set aside for agriculture by the Government. We get only a small pittance. In the annual report of the Secretary of Agriculture for 1913, comprising 48 pages, a great deal is said about foreign meats, seeds, sub-tropical fruits, corn, wheat, buckwheat, and potatoes. Even dashens are mentioned, but not one word about bees.

This Association ought to have a committee appointed to see that these discrepancies and omissions do not occur again. If the National Association does not get back of the Census Bureau, the same mistakes and omissions will occur again.

Mr. Jager believed further that the National should have a standing lobby at Washington when Congress is in session. He deplored the efforts of the National to commercialize, as it had been trying to do during the last two or three years, when there was great and important work that ought to be done. Heretofore we have been trying to stick our fingers into the water and then trying to find the hole afterward. It is time we should be doing something. We should appear in *person* before the Government, not in the form of petitions.

This address was roundly applauded; and at its close, Dr. Phillips (supplementing what had been said) went on to explain that, of the sum now devoted to the investigation work in apiculture, not one penny of it had been secured by the National Association.

There was another paper, by Dr. Phillips, on the subject—

DEVELOPMENT OF THE HONEY MARKET.

While he discussed the various methods for doing this he dwelt particularly upon the inadvisability of the association undertaking it on a national scale. He touched upon the subject of co-operation, both local and national. As the subject is naturally one that will provoke controversy, the author's exact words should be taken, and not a digest of them. It was one of the most carefully thought-out papers that were read at the convention. For its full text the reader is referred to the report that will be published in the *Review*.

These various suggestions, so far as they related to policies of the National Association, were incorporated in a set of resolutions that were unanimously adopted.

In conclusion we may say that President Gates made an excellent presiding officer. On the whole the convention was a great success.

Dr. C. C. Miller

STRAY STRAWS

Marengo, Ill.

THE winter with its blanket of snow has been fine for white clover, but I'm afraid of the present daily thaw (March 1) with the thermometer at 25 or 30 degrees each night.

WHEN I read of the wonderful work Billy Sunday is doing, I feel proud to think that I live in Marengo, one of the very first places he visited with a series of meetings when he started out on his remarkable career. I believe heartily in Billy Sunday.

THE *Prairie Farmer*, Feb. 13, contains seven articles in reply to inquiries about sweet clover, occupying nearly two pages, and it isn't a special sweet-clover number either. One man in Illinois contemplates sowing seven acres in sweet clover, another forty. That "weed" surely seems coming to the front.

BEES never had less attention from me in winter before. First part of winter was so cold the outside door could be kept nearly shut all the time. Of late, with 25 degrees at night outdoors and 35 daytime, I leave open, day and night, the door opening from outside into the furnace-room, and daytime I keep shut the door between furnace-room and bee-room. That takes the bee-room down to 48 through the night, and up to 55 daytime. Not ideal, but not so very bad.

"OILY waste," says Editor Bixby, *Western Honey Bee*, February, p. 5, "is excellent to start the smoker with . . . but it burns out to a fine impalpable soot that blows out of the smoker on to the comb. I spoiled several sections of comb honey while experimenting with it." Don't know how that is here; but my assistant has a notion it makes the bees cross. [We use the oily waste all the time, and cannot see that the bees are any crosser than they should be. May be they are used to it.—Ed.]

DOUBLE telescope covers are warmer than single-board covers, according to page 90, but some will object to their weight. To such let me commend covers like mine, with dead-air space—light as single-board covers, and much warmer. [But they are not heavier. They are made of two separate pieces—a super-cover and a telescope cover. This makes it possible to use packing material between in cool or cold weather. A two-piece cover takes a little more time to handle, and may not be as handy as yours. But yours you cannot pack.—Ed.]

IN AMERICA it is the general belief, I think, that, taken all in all, sugar is just as good as honey for bee-food. In Europe there is more of a belief that sugar is deficient as a substitute, and some even go so far as to believe that feeding sugar is to blame more or less for failure of the harvest. The subject is of so much importance that I may be excused for again referring to some things said in back numbers of the German bee-journals; for if the Germans are right we are wrong, and we may do well to find it out. Their argument is this: Besides invert sugar, honey contains pollen, ethereal oil, tannin, malate, tartrate, oxalate, and nitrate of potassa, different phosphates, manganese, natron, silica, sulphur, lime, iron. These things are necessary in the makeup of a bee's body; and although sugar may answer as a heating material in winter, when it comes to supplying material for rearing brood and to repair the waste of mature bees in activity, honey, and not sugar, is the thing needed. So it comes to pass that when sugar is used in spring bees are slow to build up, and attain full vigor only when the harvest is well along and bees are present that have been reared on real honey. Are the Germans right or are we?

FRIGHTFUL indeed is the statement, p. 212, that 4.45 per cent of the American population are drug-users. Well, it's not as dark an outlook as it might be. For not ten hours before I read that statement the new federal regulating act went into effect that has struck terror to the hearts of both vendors and users of cocaine, heroin, etc. In the Chicago *Herald* a dispatch dated Springfield, Ill., Feb. 28, says: "Pathetic pleas received by Gov. Dunne from 'dope fiends' who threaten suicide unless they are given aid in procuring drugs after their supply is cut off by the federal regulating act, which goes into effect at midnight, have brought home to the state administration the suffering the new law will bring to thousands in Illinois." Each writer asserts that he has been a habitual user of drugs for years, has tried to quit and cannot, and asks the state to furnish specified drugs in gradually diminishing doses, with the certainty that if this request is not complied with there is nothing left but death. Likely, however, when they find they can't get the dope they'll manage to rub along without it. Even if they should all commit suicide it might be a cheap price to pay for shutting off the further crop of victims.

J. E. Crane

SIFTINGS

Middlebury, Vt.

I never expect to visit Brazil; but looking at that cover picture for January 1 is almost as good, and a great deal easier.

The editor says, page 2, Jan. 1, "The best time in all the world to move bees from outyards to home cellars is when there is good sleighing." He hit the nail squarely on the head that time.

According to a bulletin issued by the U. S. Department of Agriculture, cane sugar contains 1.27 per cent of ash, while beet sugar contains 2.56 per cent. This may account for the prejudice against beet sugar as a winter food for bees.

Dr. Miller says, page 51, Jan. 15, "With almost any kind of bees I think there will be an occasional colony that will have watery sealing." Did he ever see any watery sealing of surplus combs filled by black bees?

If the GLEANINGS schedule for 1915 were not already so full of special numbers I would suggest one on sweet clover. [We have an immense amount of material on this subject—nearly enough for such a special number.—ED.]

I am glad to see on page 66, Jan. 15, that C. H. Clute, of Palmetto, Fla., has had a good crop of honey the past season. Mr. Clute is an exceedingly intelligent beekeeper, and has had a very large experience with bees in different sections of the country.

"Skunks, skunks, skunks," shouts Mr. Chadwick, page 970, and I will echo from this side of the continent, "skunks, skunks, skunks." If they do not do as much harm here as on the Pacific coast it is doubtless because they are more hunted for their furs. They are the same scamps here as there, and I have found Mr. Chadwick's remedy very effectual. But we have to look out for our neighbors' dogs and cats.

On page 925, Dec. 1, in a footnote the editor says that stimulative feeding can seldom be practiced in the spring to advantage. I fear he has forgotten the fact that very frequently we have two or three weeks between fruit-bloom and clover when very little

or no honey or pollen is coming in; and unless there has been a good flow before this, and the hives well supplied with honey, feeding not only pays well, but is sometimes of the utmost importance.

Mr. Wesley Foster, page 927, December 1, thinks we may estimate the cost of a pound of honey very accurately. We may be able to estimate what it has cost to produce a given number of pounds in any past season; and by getting the average for a good many seasons forecast what it is likely to cost in the future; but our seasons are so variable that I believe it is utterly impossible to tell accurately what the cost of honey is going to be to the producer this year or next year, or the year after.

Hildreth & Segelken, in the market report on page 5, Dec. 1, say, "We have had a good deal of trouble with New York honey on account of its candying and granulating. Shipments which we received a month ago are now candied solid, and are being returned by us to our customers. It is the first year we have been in the business when we have had so much comb honey candied." This trouble is also prevalent in western Vermont. I have wondered if it were not owing to the gathering of honey from unusual sources. While clover gave very little honey in 1914, dandelion and vetch appeared to be our chief source of surplus honey.

Dr. C. C. Miller, page 51, Jan. 15, calls attention to a statement in the *British Bee Journal* that extracting-combs put away wet will not be attacked by bee-moths, and gives as an illustration a pile of wet combs with dry ones in the center which were all eaten up while the wet combs were unharmed. To this the editor of GLEANINGS wisely remarks, "This is interesting if true."

Now, this statement, like many others, is partly true and partly false. If wet extracting-combs are white and clean, free from pollen or dead bees, the larvæ of the wax-moth will not develop on them. If there is pollen in them, these worms will develop in spite of the statement in the *British Bee Journal*; but if there are mixed with the pile of wet combs some dry combs the worms are likely to leave the wet combs when quite small and take to the dry ones, and eat them up and leave the wet combs unharmed. [See what Louis Scholl says in his department.—ED.]

BEEKEEPING IN CALIFORNIA

P. C. Chadwick, Redlands, Cal.

Unite your weak colonies, secure your honey crop, then divide just at the close of the season, thus getting service out of two weak colonies that neither alone could have given, and still maintain the original number of colonies.

A bee heavily laden with pollen became chilled before reaching its hive. It was forced to alight, but failed to take wing before it was accidentally washed from its position by a flush of water. It became soaked, and was washed to the ground. Mrs. Chadwick carefully picked it up and placed it on top of a warm hive-lid in the sun. After a time it regained its usual activity, but for some reason removed the pollen from its legs before trying to continue its journey.

As much old honey as possible should be taken from the extracting-combs before the flow begins if a light grade of honey is expected. Most of our southern California bees have more honey than they will be able to use before the new crop comes in. The larger part of this left-over honey is dark and inferior in grade, and, if blended with the new crop, it will cause it to be off in color with a resulting lower price. It is not safe to extract close, however, for a week or ten days of bad weather when a colony has much brood and many bees will put them on the starving list. A number of combs set aside and not extracted are worth much at such times. In fact, if the season is doubtful it is much the better plan to set all surplus honey away in the combs until the season is far enough advanced to enable one to know whether it is best to extract or return it to the hives. Remember sealed honey is superior to sugar as bee food. Do not remove it so closely that it may discourage the free use for breeding. Do not try to remove old honey after the combs are partially filled with raw nectar. The result will be that you will have a lot of sour honey on hand that is neither fit for feed nor for sale. It is a good plan to keep a few cases on hand in case of need for feed.

Mr. H. hired a small boy to assist him in his work with his bees. The boy was at the question-asking age, and kept a continual line of questions coming all of the time.

One hot summer day Mr. H. and the boy were slowly traveling up a mountain canyon toward Mr. H.'s apiary. Even the old horse seemed to have been affected by the drowsiness of the occasion. Mr. H. was in a deep brown study, while the boy was asking questions without number. Mr. H. answered in a half-conscious manner to fill only the place of courtesy. The boy said, "Mr. H., how many bees are there in a hive?"

Mr. H. lazily said, "Oh! about 40,000."

"How much honey will a bee gather in a year?" said the boy.

"Oh! about half a pound."

There was a sudden change in the boy's voice, and Mr. H. came out of his stupor in time to hear the boy say, "Twenty thousand pounds! Mr. H, you are the biggest liar I ever heard of."

Mr. H. could but catch the mirth of the occasion, and had to agree that he might have estimated too high.

What has become of our foul-brood bill? I have heard nothing from it since our state convention. However, I must admit I am not very enthusiastic over it, for the reason that its passage seemed to me to have degenerated long ago into a political matter, especially after it was decided to force it on to the Governor with the same objectionable features it contained when he refused to sign it before. It lacks entirely one provision of great importance. It has no provision that will do away with selfish county ordinances that we have to contend with, and of which there is a chance for as many different kinds as there are counties. There should be a freedom of commercial shipments from place to place. One inspector's work should be equal to that of any other. When a shipment of bees goes to a county line with a health certificate from an inspector they should be admitted on that certificate. The traffic in bees should not be stifled by local ordinances that really have no object except as a pretext to keep other bees out. As an illustration I will cite the fact that my apiary is in Riverside Co., yet my home and a part of my bees are in San Bernardino Co. I often wish to take bees and fixtures from place to place, and such an ordinance would be an intolerable nuisance to me, though I never move bees from either place to the other without inspection.

BEEKEEPING IN THE SOUTHWEST

Louis H. Scholl, New Braunfels, Texas.

"Spring cleaning time" will soon be here again. It is the time when our apiaries should receive a general overhauling and cleanup. It is just as necessary and essential to have these apiary cleanup days as to have them in our homes.

And don't forget the honey-house and the workshop.

"What a difference between the North and the South!" was an exclamation that slipped from my lips when reading one of the recent numbers of GLEANINGS. Ice and snow, bees in the cellars or stored away in winter cases of various kinds, many of the apiaries covered with snow several feet deep. How different it was here! Our men have been visiting our yards and preparing the colonies for the opening of spring. They were still taking off supers of fine comb honey. On some of the hives there were as many as four and five of these filled supers of white honey. The weather was fine, and quite warm on sunny days when it did not rain. We had much rainy weather, or the weather might have been still nicer. Once in a while we had cold days, but all in all it was very different from that up north.

Snow? Yes, we had some snow on the 18th of January. Every thing was beautifully white early in the morning, as there was about an inch of it.

ESTABLISHING NEW APIARIES.

Our men are now busy equalizing the number of colonies in our apiaries by moving away to new locations all colonies in excess of forty. We usually do this every spring. The forty-colony apiaries are increased in size before the honey-flow by about ten colonies, and often by about that many more in the fall. Thus the main honey-flows are taken care of by fifty-colony apiaries, more or less, which we have found to give us better results than larger yards. During the following spring these are cut down again to forty colonies, and the surplus moved away to form as many more forty-colony yards as we have bees for them.

WORKING UP A RETAIL MARKET.

Ira Davis, of Taylor, Texas, has a unique method of establishing a market for his honey. He produces chiefly extracted honey, and during the honey season devotes all his efforts toward producing a large crop.

He utilizes the more or less idle time of the winter months in disposing of this honey. He proceeds to a town or city of fairly large population, to which he has shipped ahead of him a quantity of honey in 60-lb. cans, and starts at once to establish a honey-bottling business to furnish the retail trade with honey in glass. As soon as he has this well started he turns the business over to a responsible person, either by sale or other arrangement, and with the condition that he furnish the honey for this business. Under his present arrangement and prices this is fairly profitable to both parties to the agreement.

CYPRIONS TO PREVENT MEDDLING.

An enquiry for Cyprian queens has just reached me. They are wanted to stock an out-apiary with the "most vicious bees obtainable so as to keep meddlers away who have disturbed the apiary occasionally, and at the same time give bigger honey yields than Italians or blacks." While I have tried almost all the varieties of bees, the Cyprians among them, I am still of the opinion that the three-banded Italian is superior for all-round purposes. And while the Cyprians are more vicious I doubt the advisability of introducing this race into an apiary for the purpose stated. The chances are that the meddling would go on just the same. The Cyprian bees would not give any larger yields, and the disadvantages resulting from the handling of bees of such reputed ill temper would be found exceedingly unpleasant. Wiser to prevent the meddling by some other means.

THE DENVER CONVENTION AND THE PROGRAM.

It is too bad that one cannot be at more than one place at a time. I should like to have attended the Denver convention. Well do I remember the last Denver convention I attended a number of years ago, and the enjoyable and profitable time spent at this convention and my thirty days' sojourn through the greater part of Colorado on a trip of investigation into apicultural conditions for the Department of Entomology of the Texas A. and M. College.

One thing in connection with the program of the present convention that has been of considerable regret to me was the entire absence of beekeepers from the southern states. One from Cuba was on the program. Does this mean that we are not a part of the National Beekeepers'

Association, or not worthy to receive at least some recognition? I believe that Texas, at least, has quite a few members in the National, and I also feel that we have some beekeepers down here who are well enough posted on apicultural matters to deserve at least a place on the program of the association.

WET EXTRACTING-COMBS AND BEE-MOTH.

There seems to be quite a difference in locality if we compare the doings of our bee-moths here in the South with the incident quoted by Dr. Miller on page 51, Jan. 15, from the *British Bee Journal*. My experience in beekeeping here in Texas has given me much information on the bee-moth problem. I have learned that moths not only play havoc with dry combs as soon as these are left without proper protection, but with wonderful rapidity they destroy wet combs that have been extracted only a few days before. Yes, they even go so far here as to pay no attention to the quantity of honey there may be on the combs or in them. Whole stacks of supers of comb honey will be ruined in a very short time if left unprotected at any time during spring, summer, and fall.

I have had some sad experiences. Our assistants were unable to extract promptly a large amount of honey brought into the honey-house. The first sign of these bee-moth depredations is the amount of leaking honey on the floor; and in one instance in which other important duties delayed the extracting work for more than a week, the honey-house floor was covered almost entirely with half an inch of such honey. Over four gallons of it was scraped up from the floor and set aside for feeding purposes. During the extracting of these infested stacks of honey we found scores of combs, the entire lot of which were nearly all filled solid with honey, and well capped over, riddled to such an extent that the remaining mass of honey, what little wax was left, and the webs and moth-larvæ, fell out of the frames when they were handled. From the damage done in instances of this kind I can hardly believe that the bee-moths would ignore wet extracted combs just because they were wet, although they may have a preference for dry combs. My explanation for the case cited by W. Herod in the *British Bee Journal* would be that the dry combs were infested with some bee-moth eggs or young larvæ, perhaps, left undisturbed when stacked up with the wet combs. These then developed to maturity and found sufficient sustenance upon these dry combs without having to go to the wet

combs in the adjoining supers. I venture the assertion that depredations upon the adjoining wet combs would have been made if a large number of larvæ had needed more food for their complete development. [See what J. E. Crane says in his department.—Ed.]

PREPARING FOR SWARM PREVENTION.

Already we are fixing up our colonies with the view of cutting down swarming as much as possible. Since our colonies are in excellent condition, strong in bees, the hives full of stores, and as the weather has been quite favorable, the colonies have been rearing brood to quite an extent. If such favorable conditions continue, the hives will soon be very populous. It would be sinful to try to keep them crowded down in a ten-frame hive as used to be the fashion. And, by the way, our two shallow-story brood-chambers have a comb surface equal to twelve Langstroth frames. But even this is not enough in the spring, so we are busy at this time to provide every colony, that is not already so equipped, with a super partly filled with combs of honey, some empty combs, and some frames filled with full sheets of foundation. That will give additional room in which to store any of the scattering honey that the bees begin to store, early in the year, above the daily needs, besides affording a storage place for any honey that is moved from out the brood-chamber proper in making room for the queen to lay the increasing number of eggs. A little later the queen will find additional laying room in the added super. The bees are also given an opportunity for new comb-building in the frames with foundation.

The result will be that the colony will remain contented longer on account of the ample room furnished in the manner described, there will be stronger colonies from the fact of the increased breeding room, and there will be less desire to swarm, due to the fact that there is not the crowded condition that colonies are subjected to under the old method of management. A little later, if it becomes necessary at all, we sometimes interchange the two shallow stories of the sectional brood-chamber proper, placing the lower one on top of the second shallow story, replacing the super back on top, and swarming is delayed for several weeks longer, and usually prevented altogether by the time our early honey-flow begins. When these have begun there is no more swarming. But, after all, the secret is to begin to prevent swarming before the desire to swarm has ever awakened in the colonies. Remember that.

CONVERSATIONS WITH DOOLITTLE

At Borodino, New York.

AN APIARY RECORD.

"I desire to keep a record of each colony. Up to the present I have trusted to memory regarding the condition of the different colonies in the apiary; but as their numbers increase I find memory inadequate. As soon as the snow goes off I propose to lay out my beeyard in rows and number each hive, beginning with one on the first row and going to 20 with that row; then commencing with 21 for the second row and ending with 40, and in this way continuing till I have 100 colonies in five rows. If I desire more than the 100 colonies I will start an out-apiary laid out on this same plan. Will you tell me some of the ways practical beekeepers keep a record of their colonies?"

It would seem that there should be a *best* way for this record-keeping; but there is a rare faculty which beekeepers have of thinking that the way in which they commenced must certainly be the best. Some successful apiarists tack a piece of section on the back of the hive just under the cover; and after each inspection of the colony inside this hive, any thing necessary regarding its condition is jotted down by a few shorthand characters or letters which tell all they wish to know about that colony during any season. This bit of section is left on the hive until the next spring, when the colony is looked over at the opening of the season, when, by glancing over the last year's record, the memory is refreshed regarding the colony's previous standing. The old record is pried off and the record for another year is established on a new piece. If the colony proves to be of special value, then the old piece of section is tacked on the under side of the cover, and preserved, so that a continuous record can be maintained for a term of years, or as long as particular interest attaches to the inmates of that hive.

Other successful apiarists are sure there is nothing equal to a book to keep a record in. Years ago I visited an apiary where the proprietor had kept a book regarding it for twelve years, giving a leaf to each colony, and a line of this leaf for each year. The side of the first leaf next the front cover briefly explained the signs used, while the opposite side of the leaf was devoted to colony No. 1 of the apiary. Page 1 and line 1 had all to do with the kind and age of queen, swarming, etc., for the first year,

while the first line on page 2 was used to tell how many pounds of honey colony No. 1 gave the first year, how much had been expended on it in feed, or for any other expense, thus giving the net result by taking the expenses of the colony from what the honey sold for. The second year, line No. 2 was used on pages 1 and 2 for this same colony, and in this way this apiarist had on one sheet all about colony No. 1, and what it had given him in net profit for twelve years. And as each page had twenty-five lines, this book was still good for thirteen years more for colony No. 1. Colony No. 2 had pages 3 and 4; colony No. 3, pages 5 and 6, and so on according to the number of colonies in the apiary.

This looked more businesslike than any thing I had run across up to that time; and when he told me of the enjoyment he had in looking that record over during the cold winter evenings, and the plans he made for each colony during the coming season, I was quite sure that this was the best plan. But when I came to carrying the matter out I found that the wind would shut the book so unceremoniously, and, in spite of my best endeavors, open it in a wrong place, that too much time was wasted. Not only this, the honey and propolis the paper absorbed from my hands would so stick the leaves together as to make it very disagreeable, and partly obliterate much of the record unless I carried water and a towel along with me.

I next adopted the record-board plan, as it is styled by those using it, and see no reason for using any thing else. Little squares are laid out for each hive—each in its place, and each row shown in squares. Each square is numbered the same as its hive, and in these squares I make a record at each manipulation, giving by brief signs the condition of each colony and its needs as to queen, stores, brood, preparation for swarming, etc. A board 12 x 20 x $\frac{3}{8}$ made smooth on both sides will answer very nicely for an apiary of 100 colonies. Then with this board before me I have the apiary spread out to my gaze at any time I may wish to know about it, and from it I lay out my plans on any rainy day or when I am sitting in the shade for a brief rest from the hot sun on some July or August afternoon. Now, I do not say that this record-board is the best, but that it suits me the best of any thing I have ever tried.

GENERAL CORRESPONDENCE

THE EDITOR'S CRUISER TRIP UP THE LOXAHATCHIE RIVER

BY E. R. ROOT

Our cruising party arrived at Jupiter, Florida, a little town where is located next to the largest wireless station that Uncle Sam owns. We tied to the government dock, got our supper, went to bed, and next morning we waited for Harry DuBois, the bee-man who was to meet us by appointment. We did not have to wait very long, for he soon came up with his gasoline-launch. Our party left the cruiser up at the dock and started with Mr. DuBois in his launch up the Loxahatchie River to see the country, study the flora, and stop at Mr. DuBois' outyard.

After an hour or two we drew up to one of Harry's outyards, as shown, Fig. 1. This shows his manner of protecting his hives from the intense heat of the sun. You will note that the apiary is shaded in much the same way that is done in Arizona, where the heat of the sun is intense, with this difference, that Mr. DuBois does not use a solid cover, but rather open slat work—just enough to break up the solid rays of the sun. At times he finds that this overhead

shed is insufficient, and so he uses in addition an extra shade-board, or, rather, a sheet of galvanized roofing, which is separated from the cover proper by a couple of cross-cleats.

We were about to go into his yard when Harry suggested that we had better put on our veils—a wise precaution as subsequent events proved; for the bees met us more than half way. But they are great honey-gatherers, and that was a consideration with their owner. After catching a snapshot of the yard, and looking into a few colonies, we went back to the boat to resume our delightful ride up that beautiful river. There was not a breath of air stirring, and the surface of the water was like glass. Large fish could plainly be seen under us. At every turn new beauties presented themselves. The water was so placid that it mirrored the surrounding scenery down into the river; and if we could by some means have been turned upside down we should scarcely have known which was the real and which was the reflected image. Fig. 2 gives

FIG. 1.—Harry DuBois' apiary on the Loxahatchie River, Florida. The idea of the overhead screen is not to shut off the sun's rays entirely, but to break them up. Too much shade does as much harm as too little in this country.

FIG. 2.—One of the beautiful views on the Loxahatchie River over which the editor and his party cruised.

a mild conception of the beautiful views on the Loxahatchie.

I should like nothing better than to spend a week fishing on this river—especially if I could have an expert fisherman like Harry to tell me what I did not know about the sport, and that would comprise a volume.

After we had gone up the river some twenty miles we came back and stopped at Harry's home. It is built on some shell mounds of a prehistoric race that evidently lived on oysters and fish. By digging into the bank we could find here and there fragments of old pots and kettles.

In going up and down the river that day I noticed acres and acres of scrub palmetto; and as the land grew better in spots this palmetto grew larger. The stunted growth of the palmetto on poor land, said Harry, does not permit of its yielding much honey; but where the land is good the palmetto reaches a height of six or eight feet, and then the yield of honey is fair. As everywhere else in Florida, the flow is in direct proportion to the richness or fertility of the soil. This is especially true on the Loxahatchie River. Pennyroyal comes in to help build up the colonies. Without it there is not much hope of a crop except by direct feeding, and the yields of honey are so light in this locality that Mr. DuBois says he cannot keep more than thirty or forty colonies to the yard. This is a very different condition from what we found on the Apalachicola River, where it is possible

to put ten times that number in a single location. From a general survey on the Loxahatchie one is forced to the conclusion that this is not an ideal bee country; but it makes a fair living for one man providing he can have all the territory to himself, and provided, also, that he can devote the off seasons to fishing on the river or out on the ocean. Mr. DuBois is not only an expert beekeeper, but he is a skillful fisherman as well. When he first came down into this country he went into truck-gardening; and while he got fairly good results it did not pay him as well as beekeeping. Ever since he has taken up bees he has made a better living than with gardening or fishing alone.

Speaking about fishing reminds me that at Jupiter and Pompano, a little below, is where the famous Pompano fish are caught. These fish retail at a dollar a pound. There is probably no fish in all the world that will compare with this particular fish for the table. At least I never ate any thing their equal, and I am told this is the verdict of every one who has tasted them.

The Loxahatchie is no bee paradise, whatever we may say of its beauties from a scenic point of view; and for this reason Mr. DuBois will not be interrupted in the quiet possession of his territory.

Before we bid good-by to our friend we must take a picture of him and his wife. Fig. 3 shows them on the porch overlooking the Atlantic Ocean.

The next morning we started off on our

FIG. 3.—Mr. and Mrs. Harry DuBois, of Jupiter, Fla., on the front porch overlooking the Atlantic Ocean.

cruise to Pompano, a location formerly owned by Mr. O. O. Poppleton, referred to an issue or two back, and where The A. I. Root Co. now owns and operates a small beeyard under the direction of Mr. W. A. Selser, who is now in Florida. We arrived at the place toward night. Fig. 4 shows the remnants of Mr. Poppleton's beeyard in the background and a vigorous date palm at the right, and Fig. 5 a general view of the surroundings. Here lives Mr. I. I. Hardy,

who runs quite an extensive truck-garden. At the time of our arrival there had been a frost—the only one in several years; but severe enough to freeze down acres and acres of tomatoes. Many of the truck-gardeners along the way that morning were very blue. While the Pompano vines were touched slightly, no great damage was done.

It will be remembered that Pompano is the place mentioned by Mr. Poppleton where bees could breed every month in the year. In fact, it is the location he used for years for building up his colonies. It affords large amounts of pollen and some honey clear on through the year. There is only one objection, and that is the number of dragon-flies that come on in April; but usually Mr. Poppleton can avoid these by moving his bees to other locations, and where there is honey too.

The A. I. Root Co. has purchased from Mr. Poppleton the bee rights and his build-

FIG. 4.—The Pompano location in Florida where The A. I. Root Co. now has a small apiary. The palm on the right is characteristic of this south land.

ings. We are experimenting in this location with the view of seeing what can be done in the way of breeding bees there every month in the year, and then shipping them north. The question of freights will probably be considerable of an item; but we hope we can deliver them by boat to New York or Philadelphia, and then distribute the bees from those points. In case a pre-

liminary test proves to be satisfactory we probably shall keep a man there a good part of the year to rear bees and queens. But nothing will be done during April on account of the dragon-flies. We are waiting to see how destructive they are to bees, and hence we have only fifteen or twenty colonies there. If the increase is satisfactory we shall have more.

WINTER STORES; SUGAR SYRUP PREFERRED FOR COLD WEATHER; SEALED HONEY FOR BUILDING UP IN THE SPRING

BY GEORGE SHIBER

Much has been written during the past year or so about the difference between sugar syrup and natural stores for winter.

My experience in wintering many colonies during a number of years indicates that, for a strictly winter food, and by that I mean the cold-weather food, nothing equals sugar syrup. I am also prepared to believe that ten pounds of sugar will not make much more than that number of pounds of stores after the bees have been fed. I also feel from observation that ten pounds of sealed honey will go further (during the cold weather) than ten pounds of sealed syrup. The reason why syrup is better for the confinement period is because it is easier on the bees. They can stand a long-

er confinement and come out healthier than on natural stores. I have noticed this many times. To-day, Feb. 19, the bees that had sugar are small, lively, and healthy, while those colonies that had only natural stores have touches of dysentery—not bad, however.

If my bees can have a fly some time the last of January I feel perfectly safe with fall honey; but if they cannot have this chance it is more or less risky. But with sugar syrup I would not worry if they did not fly before March.

I have had colonies winter on sugar that, after their confinement, showed absolutely no spotting of the hives when they had their flight. The spotting is always evident

when the bees have wintered with natural stores. That is my observation. For building up in the spring, whether the bees were wintered out of doors or in the cellar, nothing equals sealed combs of natural stores.

Here is my ideal way of preparing a colony for winter. We will say the hive contains about fifteen or twenty pounds of sealed stores. Some time during the last of October (as late as we can) the colony is given a ten-pound pail of two-to-one syrup. Sometimes it is a little richer than that. This will last the bees pretty well

through the cold period, and they use the natural stores to build up on in the spring. This is by far the best plan for successfully getting the bees over the winter period that I know of. This colony will probably consume more than the ten pounds of syrup before cold weather is over, when, of course, they would begin on natural stores, so if they did not fly until March the residue from the smaller amounts consumed would not be great enough to interfere with their health.

Randolph, N. Y.

INDIANA NOTES; GEE OR HAW?

BY S. H. BURTON

When doctors disagree, it's time for plain fellows to get together. There is an interesting difference of opinion concerning what the beekeeper should do in the way of using sealed covers or absorbent cushions. Why not let nature and the bees settle that themselves? Man thinks himself pretty smart in that he can improve on nature's laws, which, to a certain extent, is true; but in some cases it were better if we be not so self-conceited. Why do the bees glue up every thing air-tight at the approach of cold

NEED FOR A LARGER PACKAGE.

I wish some manufacturer would turn out a glass-front shipping-case of just the right dimensions to hold eight shallow extracting-frames $4\frac{1}{2}$ inches deep. The consumption of honey can be more than doubled by marketing it in larger individual packages. I have always maintained that the section box is too small a package for the average family. Place a section of honey on the table where there are children, and what is

weather? I have cut a good many bee-trees, and have yet to find one with any kind of ventilation at the top. I have bought and transferred a good many colonies in old box hives and gums, and the colonies were invariably strong. The inside of these old homes would be varnished over with bee-glue an eighth of an inch thick.

It is perplexing to hear so many authorities disagree; but it is the man who goes to the bees himself for an answer who finds success within his grasp.

Whether we gain by heeding Gee or Haw depends on how near we are to what nature intended, and we at least strike a happy medium.

The framework is like that of a miniature house.

left for the next meal wouldn't start a case of robbing among the bees.

Several advantages are gained in marketing comb honey in the shallow extracting-frame—viz., a greater surface of comb is exposed, giving a better appearance, which attracts the eye of the consumer; it will stand shipping better because it is more firmly attached to the four sides of the frame; it will increase the demand for honey through increased consumption, and can be produced for less than the section honey. Actual sales at four leading grocery stores showed the startling comparison that one shallow extracting-frame was sold for every single section that was purchased, the section honey retailing at 20 cts. per section, and the shallow extracting-frames selling for 75 cts. each, or 15 cts. per pound. A glass-front case was made to hold eight of these frames. All frames but the one next to the glass were wrapped in oiled paper and tied both ways with yellow "baby ribbon," which is about $\frac{3}{8}$ inch wide. This makes a neat, attractive, and fast-selling article.

A NEW HIVE-ROOF.

Has any one tried a shingle roof for a hive? The accompanying photographs show one as constructed by a beehive manufacturer here. His claims for this cover are that, since it is constructed like the roof of a house, it affords ample ventilation in summer; is as waterproof and durable as a shingle-roof house, and cannot warp nor get out of shape.

The framework—that is, the rafters and bottom plate—are cut and constructed on the order of a miniature house roof, and the shingles are nailed on the same as on any shingle roof.

I have tried this cover for several seasons, and find that it is all the owner claims for it. However, my chief objections to such a cover are that it is heavy and cumbersome, and cannot be stacked for storage compactly. It also has to be handled very carefully in order not to knock the shingles loose.

For a hive cover for the eight-frame hive I am using a cypress board one inch thick, 16 inches wide, and 22 inches long. Across the ends I nail an inch-square oak strip and clinch the nails on the under side. These inch oak strips prevent warping, and add sufficient weight to the cover to prevent its being easily blown off. Properly painted, these covers last for years, and cost about 25 cts. each.

SUCCESSFUL TRANSFERRING.

Transferring to cure American foul brood after the fall flow has ceased is usually deferred until the following spring; but we

have adopted the following plan with good success: To do the work safely, select bright cool mornings in the latter part of October, when there is no danger of other bees flying, and do the work on the "installment plan." Begin by removing the two outside brood-frames; close up the hive and put the two frames out of reach of the bees, being careful that not a drop of honey is left exposed. The following morning, if the weather is favorable, remove two more brood-frames, shaking or brushing the bees off into the hive. Follow this procedure till only two frames are left in the middle of the hive. Late in the evening part these two frames and slip in two brood-frames between with full sheets of foundation.

Quickly remove the two remaining brood-frames and shake or brush the bees off into the hive. Spread a cloth over the frames, A shape; close up the hive, and after dark close up the entrance. Leave the bees thus 48 hours. Have a new hive prepared with full sheets of honey, removing two cen-

The cover is built like the roof of a house.

tral frames. Late in the evening move the old hive alongside the new one; lift the bees from the old hive which are adhering to the frames of foundation, and slip in place in the new one. Some bees will also be clustered on the cloth, and this can be spread over the new hive. The remaining bees in the old hive can be dumped at the entrance. The bees quickly shaken from the last two old frames have very little opportunity of taking much honey with them. Being confined 48 hours they consume what stores they have with them.

We find that by thus transferring in the fall the bees draw out the new foundation, the queen starts laying, and we are in ship-shape for the coming of spring.

Washington, Ind.

One row of hives in the Wisteria Apiary, Riverton, Wyoming.

CONQUERING COLD IN WYOMING

BY E. H. RYAN

I am an amateur beekeeper. I have been in the business about five years, and have had many reverses in losses of colonies, but only from cold winters. It is sometimes 40 below zero here for several nights at a time.

There is only one way to handle bees successfully here, and that is to use double-walled hives packed underneath the bottom-boards with straw. The bottom-board must be ten or twelve inches from the ground.

I also use a gunny sack over the hive, under the cover, allowing it to hang down over the sides and entrance to ward off the snow.

On warm days the sack is turned up

from the entrance so that the bees can get out and fly.

I have a house 16 x 20, with a basement under it. I extract the honey in the house, and pipe it through the floor into the strainer over the storage-tank in the basement. Here it is canned up and stored. I use a six-frame automatic extractor and gasoline-engine. I have never made less than 200 lbs. surplus per colony, spring count, and some colonies have made as much as 500 lbs. extracted honey in a season.

There is abundant pasture right at hand, consisting mainly of sweet clover and alfalfa. The honey is principally sweet clover.

Wisteria Apiary, Riverton, Wyo.

SETTING BEES OUT OF THE CELLAR

How to Prevent Drifting and General Demoralization

BY E. S. MILES

The time to get the bees out seems to me more of a problem than the time to put them in. After they are in we care little what kind of weather comes, as it cannot affect the bees in the right kind of cave or cellar. But in the spring it is the other way. After they are out, the weather does affect them considerably. After the time when bad blizzards are not likely to come, or long-continued cold, if the bees can be taken out so as to get a nice warm sunny day for a cleansing flight, they will endure much bad weather and yet mature some brood; and if there are plenty of stores in the hive, as there should be, they will have a nice lot of young vigorous bees by fruit bloom to replace the loss from old age, which is quite heavy in spring.

In getting cellared bees established again on their summer stands there are two things to be guarded against—namely, mixing up and robbing. Where a lot of bees are confined to a small space for several months, as in a cellar, they do not always seem to know "which from t'other" when first set on their summer stands. This sometimes leads to robbing, which, when once started, is hard to stop. Any thing tending to confuse the bees or cause them to lose the location of their own hive, and get into another, will increase the danger of robbing getting started. To avoid mixing up and robbing we recommend the following procedure, which, while it may not always prevent, will reduce these troubles to the minimum if care is used.

For setting the bees out, choose a still sunny day, only moderately warm—from 50 to 60 Fahrenheit will do. Set out as many as possible as early in the day as the temperature will allow; put all colonies on the same stands they occupied the fall before, and contract all entrances immediately, before any bees fly. It is a help also if the apiary is located so as to contain some shrubbery or small trees or buildings, as these will divide the bees and make them notice their location better. A small apiary, less than 50 colonies, will not be as hard to manage on this score as one containing 100 or 150 colonies.

The advice has been frequently given in the journals to disregard the previous location of the hive in setting out in the spring. This is a mistake, especially in a large apiary. To those who doubt that bees remember the location of their hive over winter, we wish to recommend this experiment: When you take out your first colony, instead of setting it on its old stand set it on a new one anywhere in the apiary, having first set an empty hive, like it in looks, on the stand it occupied. Now watch the empty hive a little while and see whether any bees, after circling around, will come back to the old location. If your bees are like mine a good many will be seen hovering around the old location in a short time after the colony starts to fly. If you now set another colony from the cellar in place of the empty hive, quite likely some of these bees will alight and unite with that

colony. If no other hive was put out, however, they would soon find their own. The more hives put out, on the other hand, make it more unlikely that they will find their own.

There are certain colonies that seem to be inclined to welcome all comers; and as soon as some of the lost bees alight at these entrances, and start the "home call" it means a steady gathering of the strays, so that certain hives are packed full while others are depleted.

Another thing that tends toward the same results is to leave too large an entrance during the first flight. There is no need of a large entrance at this time except where the bottoms have been left on over winter, and the bees are expected to clean them of dead bees and cappings. It is more economical and much better to winter the colonies without bottoms, thus having clean ones to set them on each spring. But if they are on, rather than make the bees clean them we would change each one when setting out, getting a clean one to start with, and after changing the first one clean that one for the next hive, and so on, so that all have clean bottoms when through.

Contract the ordinary $\frac{3}{8}$ -inch entrance to one or two inches in width for fair to good colonies, and $\frac{1}{2}$ to $\frac{3}{4}$ inch for weak ones. This is more to prevent the bees getting into the air too fast than to prevent robbing.

If bees are set out on a windy day they are pretty sure to "drift"—that is, head up against the wind, and go into the hives on the windward side of the apiary. The only reasonably sure way to prevent this is to avoid setting them out on a windy day, although it may help some to set the leeward side out first, letting as many bees return as time will permit before putting out the windward side. Drifting is much worse in an open yard exposed to wind than in a sheltered place with trees or shrubs in it.

We have tried changing places with hives that had more than their share, putting weak ones in their place. This will equalize some, for many of these bees will go back to the same location at their next flight; but there is some chance of losing queens by this procedure. Another thing to be remembered is to air out the bee-cellar thoroughly if possible, the night before taking the bees out. If this is done the bees will be much quieter, and will not notice the fresh air that comes in when the door is opened to enter the cellar as they would if the air in the cellar were warm or stagnant.

We do not use any smoke in the cellar in taking bees out, but always have a good smoker handy outside, to make them behave until the hives are fixed as wanted.

Dunlap, Iowa.

THE SEASON OF 1914 IN THE CENTER OF ENGLAND

BY W. J. WOOLLEY

Being a touring expert in the southern part of Worcestershire I send you my short report of 1914.

This is a noted fruit and vegetable growing district bordering on the outside with farming. The honey crop was the best for about twelve years. Although the Isle-of-Wight disease did some little damage the district still contains a lot of strong healthy colonies, and the bees paid well.

The average in the fruit-growing district was 30 lbs. of honey. Some of the members of my association who live in the vale at the foot of the hills had an average of 75 to 80 lbs. each for which they received the price of 9d per lb., extracted, and 10d per section wholesale.

The bees were busy from April till August, when the drouth affected the yield from the clover. Colonies went into winter well provided with plenty of well-ripened food, and look promising to come out strong in the spring. The bees swarmed very little

this year. Out of my apiary of 28 stocks I had only three swarms, and I could not get enough to supply orders for swarms.

At one place where I called on my autumn tour the man had not taken his crop of honey off, and he asked me to do it for him. He had put only one rack of sections on, and had been too busy to attend to them, so he said. Well, when I got to the hive I had hard work to get the roof off. What a sight! The owner had put only one small quilt over the rack of sections, and the bees had found a way, after finishing the rack of sections, into the empty space above, and had built and sealed with honey the whole of the space under the roof of the hive. They had sealed the roof down with honey. The bees had stored over 30 lbs. above the rack of sections.

He wished, when he saw the sight, that he had looked after them a little better, and so had a far greater crop of honey.

Evesham, Worcestershire, Eng., Dec., '14.

Bees working on flour during a dearth of natural pollen in the spring.

STRAIGHT AS A BEE-LINE; ECCENTRICITIES OF BEE-FLIGHTS

BY GEORGE H. REA

The cover picture of GLEANINGS for December 15th reminds me of a visit to this yard late last summer. It was during buckwheat bloom, about the middle of the afternoon of a hot day. We had driven out in the auto truck to feed (this is the yard where we fed the Porto Rican honey, see page 4, Jan. 1).

Very little nectar was to be had in the field excepting from a small field of buckwheat on the north side of the yard, but it was the wrong time of day for that; so that you can imagine my astonishment when entering the yard to observe the bees lining off toward this buckwheat-field by the thousands.

Now look at that picture (cover, Jan. 1). The north is at your left. Observe that there is a fifty-foot embankment to the south, or right-hand side, covered with trees. The west side, or the front of the picture, is open ground, as is also the embankment on this side of the yard.

I told the boys that while they fed the bees I would determine, if possible, where the supposed honey-flow was coming from. I intended following the bees; but before so doing several of the incoming workers were relieved of their burden, and in every case it was found to be water, pure and simple.

I was puzzled to know why they should line off toward cultivated fields where no water was in sight, when a copious stream flowed in the ravine at the base of that bank not more than one hundred feet away.

To my astonishment this is what I found: The flight was in a stream out over the fence on the north side and into the field to a point a little beyond a small tree, which shows in the margin of the picture. There they turned sharply to the east, continued over the corn-field in the background, and out over a plowed field nearly a quarter of a mile beyond, keeping parallel with the wooded ravine. Here the ravine spreads out, the high banks diminish, and the stream is skirted with low-growing trees. Here the flight of the bees rose almost beyond vision, and turned again abruptly to the right, or south, and continued to turn out over the shrubbery, and flew directly back down the stream on the opposite side.

They were found watering in a swampy place at a point almost directly opposite the apiary, most of them not five hundred feet from where they started. Why did these bees fly fully half a mile to get water so close to their hives?

Three reasons, I think; namely, protec-

The result of neglect. The bees died because disease was allowed to get a start.

tion which the trees afforded from the prevailing southwestern winds; to avoid either flying over those high trees, which was necessary if they went direct; or lifting straight up that high bank if they flew west a little to the opening. But then, talk about "as straight as a bee-line." Say! I have lined my bees at home among the Pennsylvania hills for a distance of seven miles, and

descried many a crooked path thereby; but this is the most notable case that has come under my personal observation. It is conclusive proof that bees do take advantage of the contour of the country, and natural objects, such as trees, buildings, fences, etc., in order to follow the lines of least resistance to wind and gravity.

Medina, Ohio.

REFLECTIONS OF A BEGINNER

BY C. M. MYERS

A thorough knowledge of beekeeping at the start is not essential to the eventual success of the layman; but judging from my experience a thorough study of the advanced A B C and X Y Z of Bee Culture will save many brain-storms and heartaches for the average beginner.

All one winter I studied the A B C daily, and each day some new phase of the work became more apparent. When spring came, following a hard winter, I was anxious to get started early; but because of the heavy winter losses among the beekeepers all over the country I was unable to find any bees for sale until the first of June. At that time I purchased two strong colonies with half-filled supers. I brought these to my home in town, and placed them in the back lot. This was barren of trees of any kind, and the only shade the bees had came in the late afternoon from a board fence.

My venture seemed crowned with success when two full supers had been removed and new ones substituted; but my enthusiasm was taken down a notch or two a few weeks afterward, when, in searching for queen-cells to head off any inclination at swarming, I found that both my hives were infected with American foul brood in the most malignant form. The McEvoy treatment was given them at once, and they were in fine order by fall. That winter, however, they went out just after a continued warm spell in February. Upon examination I found my error in judgment regarding the amount of stores needed, as all the stores were exhausted.

Hardly before the time when bees are safe from spring dwindling, two more hives were bought at a sale held by an expert beeman. These were placed on the empty stands. This second year proved a failure

A close view of a comb containing foul brood, showing the sunken and irregular cappings, scattered patches of brood, etc.

as far as surplus is concerned; but from these two stands an artificial increase of six was made, and, with the purchase of four more hives, the second year closed with twelve good colonies.

The winter following was a severe one, and a total loss of four occurred, two of which came because of leaky lids. This caused me to fit all my colonies the following summer with metal covers. By careful methods I was able to get good surplus last summer; but not one of the eight old stands produced as much as a prime swarm which was captured the first week in June. When winter came I had a total of fourteen colonies. The additional six were natural swarms, five of which were captured, and one was my own because I overlooked a queen-cell.

Few are the men and women engaged in the hazards of business who do not look forward to the time when they shall have a country home of their own, let it be large or small. There they hope plenty of all of life's necessities may be assured regardless of financial conditions.

That has been my sole ambition. While yet a young man, not yet out of my twenties, I hope to return to the soil whence my ancestry came. While a bank account is a

thing much to be desired, thousands of young men and women, married or single, find things seriously different from what they anticipate when they reach the end of the business world. The game requires much and gives back little in return, and absolutely nothing when old age and infirmities come with awful suddenness. Discharge from the service of the employer sometimes brings nothing to face but the infirmary when the small savings of fitful frugal periods are gone.

Therein lies the reason why so many acquire knowledge of bee culture, poultry-keeping, and gardening—that they may succeed when their backs are turned on the fallacies of the cities, and that they may return to health, happiness, and a bank account in the country.

Two years ago I had the pleasant and profitable experience of assisting the state inspector of apiaries in this section—an experience which has proved to be more valuable to me than I had ever expected. There can be no reason why any one who owns bees or keeps them in any way, modern or crude, should not be well informed on the subject of foul brood. Every farm paper of any consequence, and all of the bee-journals, have articles of this kind, and

the government has on hand at all times a supply of bulletins relating to this and all other subjects of importance.

I am sending two pictures of brood-

frames in an apiary of five colonies, which died of the disease during the winter previous to our inspection.

Winchester, Ind.

THE WATER TREATMENT FOR GETTING BEES OFF DISEASED COMBS

BY F. R. M'COY

Read before the annual meeting of the Idaho Honey producers' Association

As soon as foul brood is discovered in any colony of ordinary strength, treat the diseased colony at once by placing it in a tank containing a few inches of water. This tank must be perfectly level, and the water deep enough to keep the bees from escaping from the infected hive.

Take a clean hive, with full sheets of foundation. Place a wire cloth upon the top and put the whole thing upon the top of the diseased hive in such a manner that the bees can readily work up into the clean hive. Finally, put weights on top of the upper hive to keep the lower hive from floating.

Commence pouring water into the tank in

a steady stream, small enough so that it will take about twenty minutes for the water to get high enough to force all bees from the diseased lower hive into the clean upper one. Let the water reach the top of the lower hive, and no higher. Great care must be taken not to pour in so much as to raise the level above the joint between the lower and upper hive.

The bees are now off the old combs, and absolutely clean and free from any disease. Have a bottom-board ready on the old location where the diseased colony stood, and set the clean hive of bees on top. Take the diseased colony or the old hive, and destroy it totally by fire.

THE VALUE OF THE ADVERTISING DEMONSTRATION

BY J. L. GRAFF

There was read at the late convention of beekeepers in Chicago a letter in which the writer ventured the suggestion that if each beekeeper would contribute half a pound of honey or its price toward raising a fund to carry on a propaganda demonstrating the varied uses of honey in the average home a great deal could be accomplished in increasing the demand.

I have often wondered why honey itself is not used to tickle the palates of food consumers. I notice at the big shows, like the dairy and live-stock shows, other products are demonstrated in an effective way. Three hundred thousand people attend the Chicago international live-stock show annually. Butter on crackers advertises the butter. Butter is put into thousands of bags of pop-corn for the same purpose. The manufacturers

of ketchup make extensive use of the oyster patty to tempt people to try the condiment.

If the results that encourage manufacturers to stick to such a practice are satisfactory for butter and other products, why wouldn't a small spread of honey on a cracker turn people to honey?

Recently I went into a grocery and discovered the proprietor standing on a high ladder. He had a big poster in his hands making ready to tack it up. When he turned it right side out I read the advertisement of Airline honey. It was displayed in a taking way; the bill in itself was attractive, and there was a good catch-line that led the reader to read on.

Honey can be effectively advertised and demonstrated. The thing to do is to do it.

Chicago, Ill.

BEE CULTURE TAUGHT AT SCHOOLS

BY W. C. HICKS

Inclosed is a picture of a school exhibit at a tri-county fair recently held in Cass Lake. This is of interest, as it shows that beekeeping is taught in our schools. This is a new country, just changing from the lumber industry to the agricultural. It

gives promise of being good bee territory. Our honey-plants are white and alsike clover, wild raspberry, and basswood, with acres and acres of pollen-bearing shrubs that bloom in early spring. Sweet clover is being introduced.

Cass Lake, Minn.

School exhibit at the tri-county fair, Cass Lake, Minn. This shows what can be produced in the northland timber region. W. C. Hinks, High School Agriculturist.

At the age of 79 Mr. Sherk does all the work in his apiary.

HALF A CENTURY A BEEKEEPER

BY ETHEL LEARN

My grandfather, J. J. Sherk, who is now in his eightieth year, has kept bees since he was eighteen. His sister gave him his first colony, which was in a box hive; but that winter he lost it. The next summer his father gave him another if he would give him the honey. This was in an old-fashioned straw hive which he made himself. He used these for a number of years until he heard of the "Ott" hive; but he did not have success with that. He then tried the "Jones" hive, which he liked somewhat better, but that winter he lost all he had—fifty colonies.

He then bought another colony, for which he paid \$9.00. A friend of his advised him to try the Langstroth hive. This he liked, and is still using.

He has 61 colonies now, and does all the work for them himself. He extracts his own honey with an automatic extractor, which is much better than straining it through a cloth, which he did when he first started. He has had better success these last few years than he ever had, but last year there was little honey in this section.

Vineland, Ont.

THE PREVENTION OF SWARMING

A Sequel to the Law of Swarming Formulated

BY WILLIAM BEUCUS

There was a time when the tipping of tables and the writing of the planchette board were regarded as due to the actions of spirits. It satisfied the craving for the marvelous and the startling. But investigators proved that these phenomena are due to involuntarily muscular contraction. Nevertheless there are still to be found those who insist that spirits are the cause.

So it is with swarming. The desire for the occult has caused many of us to look with disfavor upon any explanation which shows that swarming is due to simple causes.

We do not like to think of the hard unpoetic work by which swarming may be prevented, and hope to discover some simple sleight-of-hand method by which swarming shall be easily and quickly controlled. To show that the tipping of the tables, writing of planchette boards, and kindred phenomena, as well as the swarming of bees, are due to the action of well-known causes is a cruel disappointment. Nevertheless the thirst for truth compels us to reject the poetic and accept the prosaic.

Some time ago an intelligent beekeeper

informed me that a certain beeman had discovered how to make some slight change in the brood-chamber by which swarming was entirely prevented. This man, I was told, refused to divulge his secret because the crops of honey would be so enormously increased that ruin would overtake the beekeeper. That man died, and his great secret is buried with him. Let us be thankful that he saved the beekeepers from ruin or himself from exposure.

In one of his articles Dr. Miller, after half a century among the bees, says in substance: If any one expects to be told of some easy way to prevent swarming, let him stop right there.

In the issue for Aug. 1, 1911, appeared an article by the writer of the present paper, in which the law of swarming was formulated as follows: Swarming among bees is a migratory habit which operates under conditions which render difficult or impossible the performance of their respective functions by the inmates of the hive. With the light of this definition as our guide, let us see what can be done to prevent swarming.

There are five conditions in the presence of which bees swarm: 1. Uncomfortable hive; 2. Starvation; 3. Insufficient numbers; 4. Poor or failing queen; 5. Crowding.

Let us consider these conditions in the order given. 1. Uncomfortable hive. A swarm placed in a dark-colored hive, in the boiling hot sun, without a shade-board, is almost sure to desert. Often it will also desert if placed in a hive with a small entrance. A swarm hived on starters is pretty sure to abscond; hived on full sheets it is less likely to abscond; and hived on a set of sweet-smelling full combs they never abscond. To prevent that kind of swarming which we call absconding, place the hive in the shade because bees cannot work so well if oppressed by heat. Make the entrance large enough, because bees cannot work if they cannot breathe freely. Do not give starters, because it compels the bees to do some hard preliminary work before beginning with the more important work of house-keeping. Do not give full sheets if it can be avoided, because, although the preliminary work is less than with starters, it is still considerable, and stands in the way of taking up at once the real work of life. If you can do so, give the swarm a full set of combs because it removes every obstruction to immediate beginning of the important work of life. To summarize, make it easy for the bees to begin rearing brood and storing honey. These are the two kinds of

labor for which comb-building is merely a painful preliminary. Relieve the bees of that, and they will be contented.

2. Starvation. Bees cannot live without food, nor can they rear offspring if they cannot live. Realizing this they seek a more favorable location. To prevent this, see that the bees have plenty of food at all times of the year.

3. Insufficient numbers. A handful of poorly wintered bees will usually begin brood-rearing, just as will a colony weakened through drifting when set out. It is an inexorable law that the temperature of the center of the cluster must be high in order to mature brood. A handful of bees cannot maintain that temperature, therefore the work of life cannot be carried on. Keep all colonies strong in summer, fall, winter, and spring, and you will not be troubled with this kind of swarming.

4. Poor or failing queen. In the evolution of the bee, those colonies headed by the most prolific queens had the best chance of survival. Prolificness is common to the queens of honey-bees, and the presence of a vast multitude of bees, as a normal condition, has been registered in the brain of the bee. So when a queen fails to lay many eggs, the bees instinctively feel that something is wrong with their queen, that the future of the colony is threatened, and so they begin preparations for rearing a new mother. But for thousands of years the building of queen-cells has been inseparably connected with swarming. Hence a swarm emerges as soon as the first cell is sealed, or even with the emergence of the first queen. To prevent this, keep track of the age of the queens and of their egg-laying. Do not allow queens to get older than two years, and remove all inferior queens. Young prolific queens make it possible for bees to carry on the function of life, raise an abundance of brood, and secure an abundance of food. To prove that a good deal of swarming results from superseding, remove several queens this year after the honey-flow is over, and you will find that, in from eleven to fourteen days, swarms will issue from some of those colonies while the remainder of the yard will be quiet.

5. Crowding. We come now to what I call normal swarming. I wish to state, in passing, that part of the swarming commonly attributed to crowding is due to superseding, for queens are replaced by the bees in spring, summer, and fall. If swarming is due to crowding, then of course more room must be given. By so doing we are simply making it easy for the bees to carry on their lifework, and this is all they desire.

Giving room to colonies run for extracted

honey is easily accomplished. Brood may be lifted into upper stories, and empty combs given; but it is not so easy to give room to colonies run for comb honey without sacrificing part of the crop. Shaking the strongest colonies off and allowing them to run in on to full sets of combs, at the beginning of the honey-flow, usually settles those colonies for the season. But if the honey-flow is long and the queen prolific, these colonies may need attention.

It is not at all impossible, however, that an examination every week or ten days will reveal no queen-cells started, in which case there is nothing to do. If queen-cups are found with eggs in them, these may be destroyed and swarming may not take place; but if large larvæ are found in cells it is necessary to take away all brood and give drawn combs in place.

If queen-cells are started, and eggs laid in them, and if they are immediately destroyed by the beekeeper, the bees still store honey. But if the cells become well advanced, the idea of swarming spreads and strengthens—motion gets started in the new direction, with how much force many a beekeeper can testify.

The problem then is psychological. We are first to satisfy the craving of the bees to rear brood, giving plenty of room for the purpose; and as soon as the honey-flow begins, we are to satisfy the craving for storing honey by giving plenty of room above the brood-chamber.

And now attention must be called to

something which I do not remember to have seen in print. In their wild state, bees do not labor hard to store honey. They labor to raise bees. The storing of honey is not the object; that is merely an incident. Raising brood is the real object. But man has reversed this. He has made the storing of honey his object, and so it happens that usually swarming comes from lack of room for the queen. The perpetuation of the species is the great activity of life.

To summarize briefly: To prevent swarming, see that your bees are comfortably housed, have plenty of feed at all times, are always strong in numbers, have a good queen, and, in the honey-flow, plenty of room for storing honey and rearing brood, and you will not be troubled much with swarming. To accomplish this requires a good deal of work, but it is the price which must be paid.

Since writing the above, I came across a peculiar verification of the law of swarming as I have formulated it. Dr. Miller tells us that he hived a swarm of bees on a set of drone combs to determine what would happen. The bees promptly swarmed out. Why? Because a condition stood in the way of the performance of the predominant bee function—the rearing of worker brood. It is noticeable that a swarm invariably prepares for the rearing of worker brood, and never builds drone comb until that has been attended to. This condition obviously comes under the heading, “uncomfortable hive.”

DESTROYING ANTS WITH CARBON BISULPHIDE

BY ARTHUR E. AULT

On page 70, Jan. 15, E. S. Miles, of Dunlap, Iowa, tells of his partial success in destroying ants by the use of axle grease and kerosene and a plentiful use of fire.

In my experience in keeping bees in Florida I have suffered very little loss from ants.

Two years ago, in one of my apiaries a small red ant was very plentiful. These build nests in the ground, some of the nests being several feet in diameter. They are fierce biters, and it is very annoying to work by one of their nests. The first I observed of them attacking the bees was when I found a weak colony with the comb half covered with the ants. The bees seemed greatly disturbed, and on my next visit the ants were the only occupants of the hive.

Later I formed a strong nucleus in another part of the apiary, when within an

hour the ants covered the combs and the bees deserted the hive. I then secured a pint of carbon bisulphide for which I paid 50 cents. With a hoe I dug into the ant-nest until I found the ant eggs, when I poured in a tablespoonful or more of the liquid, closing the hole and covering the nest with a hive-cover to confine the gas, as bisulphide of carbon is very volatile.

Returning to this apiary after about a week I found only a few of the ants, which I proceeded to treat as before. That was two years ago; and though I sometimes see a few ants about the apiary they are not sufficiently numerous to cause any trouble.

As will be seen, this method of destroying ants can be used only where the ant-nests can be located; but in such cases it is very effective.

Bradentown, Fla.

THE ALEXANDER METHOD ADJUSTED TO A CLOVER LOCALITY

BY IONA FOWLS

Since J. G. Brown's defense of the Alexander method for the West, p. 27, Jan. 1, I have watched in vain for an article from a clover locality bearing upon the subject. It just now happens that our honey-flow is from white clover and alsike. Also "we really keep bees and are kept by them." Therefore I shall venture to explain just how we have adjusted the Alexander plan to our locality so that we have been enabled, during the past three years, to systematize and lighten our work, and at the same time to increase our crop materially.

week, and giving every colony plenty of room. If queen-cells with eggs or very young larvæ are found, they are torn down. But whenever a more advanced stage is discovered we immediately put our system into operation.

The hive is moved to one side and replaced by one containing foundation or empty combs (preferably the latter). One of the central frames is then exchanged for a frame of brood with the queen but no queen-cells.

At this point occurs our first divergence from the Alexander plan. He advocated putting the queenless colony right on top with nothing but the honey-board between. Now, if we should do that at this time of the season the chances are that the swarming tendency would very rapidly develop into a mania, with the result that we should lose the use of those bees just when we most needed them. Therefore, between the queenless swarm and the lower hive we place at least three shallow-depth supers of empty combs, or probably two, if full-depth supers are used. Should it so happen that we are obliged to use partly filled cases between the two swarms, no harm is done provided we leave plenty of room. However (and this is very important) the super

immediately below the old swarm must be entirely empty. The new swarm below now has so little brood and such an abundance of room, and they are so far removed from the nurse bees and cell-builders, that they completely give up the idea of swarming.

Here our method differs widely from Mr. Alexander's. He waited five days; and then if there were any cells with larvæ he separated the two swarms at once. If not, he left them for ten or eleven days before separating, and then one day later he gave

THAT BEEKEEPER CONVENTION.

The members of the "convention," as they stand on and before Mr. Johnson's porch. First on the left, Mr. Wilder; next to him, Mr. Raub, the man who made such a success with an incubator after he was 80 years old; next, Mr. Clute. Last, on the right, Mr. Ratray, from Michigan. Mr. Redout is the central figure in the background. See page 251.

Perhaps I should state at the beginning that we believe it a great mistake to endeavor to prevent swarming. If you will allow the analogy, it seems to me a good teacher recognizes the value of activity in her pupils, and seeks not to prevent it but rather to guide it so that it may work out to their advantage and not to their detriment. Our plan is quite similar.

At the opening of the season we watch very carefully for the first indications of swarming, overhauling each apiary once a

them a queen or ripe cell. Not only would this require rather close attention, but it would also necessitate opening the hive three or four different times. Our plan is simpler. We tear out the capped cells above, leaving all the embryo cells, even those nearly capped. The swarm may then be left for seven or eight days, feeling certain that no queen can hatch in the meantime. At the end of a week the upper story is moved to another location; and in case the stock is poor they are given a cell from a better strain. Otherwise we destroy all but one capped cell; but if time is pressing, even this may be neglected, for the bees themselves will attend to the matter.

For our locality we find this method more efficient than any we have ever tried. Of course we do not raise twice as much honey, but no doubt we increase our crop considerably, for the bees have been given no opportunity to loaf. Moreover, we have early in the season, in addition to the old queen, a young vigorous laying queen. In the original plan, queens had to be provided in some other way; but with our variation of the method we obtain the very best queens possible, for they are raised under

the natural-swarmling impulse. We find, too, that in running for extracted honey, as we do, the extra supers between the new and old swarms come in very nicely.

It should be noted that the plan is not wasteful. There is no loss of eggs, larvæ, or brood, since at the time the hive is moved to the new location there is nothing but capped brood in the hive. But, more important still, we are no longer worried by natural swarms issuing at some outyard when no one is there to attend to them; because, except for very unusual cases (supersedure, or a swarm with a virgin), we have no natural swarms, and consequently are able to leave an apiary for a week at a time right during the honey-flow. Thus by a plan that is neither complicated nor wasteful, we obtain with less work and anxiety better queens and more honey.

We claim no originality whatever for the plan. We have probably combined the methods of different writers. However, it may be of interest to some to learn how we have dispensed with the inconveniences of natural swarming, and at the same time have retained the advantages.

Oberlin, Ohio.

BEES AND FRUIT; TWO NEW TREATMENTS

BY JOHN W. LOVE

For many years it has been necessary to attack an ungrounded prejudice against honeybees held by fruitgrowers who believed that beekeeping was detrimental to horticulture; but now that the notion has practically disappeared, beekeepers and fruitgrowers together are realizing how closely connected are the interests of each other through the service rendered by the bees. One of the broadest discussions in this field has been furnished by Mrs. Susan M. Howard, who writes on the subject, "Honeybees as Pollinizers—a Valuable Adjunct to the Horticulturist," in *Apiarian Inspection Bulletin* No. 8 of the Massachusetts State Board of Agriculture (June, 1914).

Along this same line, but narrower and more scientific in treatment, is an investigation in the development of the apple from the flower, and the value of the honeybee as a fertilizing agent in a paper of the same name, written for *Better Fruit* by O. M. Osborne, and reprinted by The A. I. Root Company.

"To-day the honeybee is more and more considered an invaluable ally of the farmer," writes Mrs. Howard. "The orchardist

and small-fruit growers consider their colonies as a part of their equipment, and their use as much a factor in the success of horticulture as is cultivation, application of fertilizers, the growing of cover crops, pruning, spraying, and the like. To the farmer, especially if he be a fruit-grower, a honey crop may be regarded as secondary or as a by-product, while to the beekeeper it is a primary product; thus while the ultimate aims of the horticulturist and beekeeper may be different, yet they are interdependent."

On account of the uncertainty of service by accidental visits of bees, the forehanded fruitgrower now provides a sufficient number of colonies not far from his orchard, if not actually under the trees. Although bees will forage for honey a distance of six miles from the hive, if necessary, it is better to have them at close range, since they prefer short trips, and do not completely work a circle of six miles in radius.

Besides the nectar, bees are in search of pollen as a food. This is a highly nitrogenous substance supplying nitrogen and phosphorus—two elements needed to sustain any kind of life. To be sure, this

pollen is provided vastly to the excess of the actual needs of bees; but its seeming over-production may be explained on the ground of an effort on the part of the plants to insure pollination.

The search of the bees for food is the occasion of their inestimable service to the fruitgrower through their unconscious part in pollination. The process is entirely mechanical, and could be performed by human labor, and has been; yet the labor of the bees is not only far more effective but incomparably cheaper. Growers of cucumbers in Massachusetts greenhouses use colonies for this purpose alone.

Turning now to the fertilizing process itself, the botanist recognizes three varieties of sex distribution in flowers, viz., (1) Both sexes in one flower, as where the stamens (male), and pistils (female), are both present and complete; (2) Sexes separate in individual flowers, but both sexes on the same plant; (3) Sexes separate on individual flowers, which are borne on different plants—a further modification of the second class. Some plants, therefore, are only male; others are only female.

Since most of our fruits and vegetables involve a sexual process in the union of the pollen and germ of the egg, there must be some means of union, especially in the second and third classes of flowers, where the sexes are separated, either in individual flowers or in individual plants. Of all the insects furnishing this means, the bees are recognized as the most important, and should be provided by the grower of fruit.

The wind is effective in transferring pollen from blossom to blossom in those trees and plants having a fine and dry pollen, as, for example, the pines. Trees which are wind-pollinated are usually independent of insects; but among fruit and vegetables the pollen is usually heavy and sticky, and depends upon an insect, usually a honeybee, for its transference. Experiments show that little or no apple pollen drifts in the wind.

The honeybee seeking nectar far down

in the flower covers herself with pollen from the stamen, or male organ of the flower, and gets it against the pistil, or female organ of that or some other flower. Thus quite accidentally has the function of the bee been performed. In this vital operation the union of the pollen left on the pistil with the ovule within completes the process of fertilization and results in a perfect seed.

Many plants are sterile to their own pollen, and require pollen from another source. Furthermore, self-fertilization is found to tend to weaken the offspring, and, in contrast, crossing or cross-fertilization is found to result in greater strength and productivity. Moreover, flowers are generally constructed to favor cross-fertilization and to prevent perpetual self-pollination.

In mixing varieties of pollen, bees serve to create new crosses and to increase varieties.

One of the most practical points brought out both by Mrs. Howard and Prof. Osborne is the fact that the apple requires five independent fertilizations for complete results. If many ovules fail to fertilize, the apple will lack size or symmetry, or both. Thorough fertilization prevents the dropping of apples.

While the number of full-blooming trees in a cluster has much to do with drawing the attention of the bees, yet high color or fragrance do not always act similarly.

It has sometimes been contended that the honeybee damages the fruit by biting into the skin and sucking out the juice. It has been shown, however, that the jaws of the bees are so constructed that it is entirely impossible for them to bite into the skin of any kind of fruit; but when the skin has once been broken the bees have an opportunity. The jaws of the bee are smooth and rounding, and quite unfit to make an opening of any kind. Wasps and birds are guilty of making the opening in the first place, and fruitgrowers should not blame the bees for this damage.

The bulletins close with remarks on spraying during blossom time.

THE INCUBATOR IN QUEEN-REARING

BY DR. BRUENNICH

The view of J. E. Hand concerning the use of the incubator as a queen-hatcher has my full approval. Many years ago I gave to the nuclei, not cells, but queens hatched in an incubator, and I find the advantages considerable. After my experiences the losses with young queens are not nearly so

great as the losses with cells. When a new nucleus is formed it is with my methods extremely rare that a young queen is killed, be she one, two, or more days old. The most important requirement is that the bees of the nucleus be young. For this purpose I take the bees of the super, and am sure

to have success. A freshly formed nucleus with such bees will accept every queen. It is somewhat more difficult to give an unfertile queen to a dequeened nucleus; and I agree fully with Mr. Hand, that it is not advisable to give another queen before three days elapse after dequeening. In this case I give the young queen in a wire tube, but do not let the bees come to the candy before one or two days. I give candy enough so that the bees have at least 24 hours for eating it, so I have only insignificant losses. The losses come later when the young queen flies out, and if there are but few traces of robbery. In such a case the queen will be balled and stung. But that is exactly the same if I have given a cell or a young queen.

A great advantage of this method with hatched queens is that the young queen can be minutely examined before giving it to a nucleus. A queen which has not the needed characteristics of the desired race is eliminated, and so is, of course, each one which is minus a claw or has a deficient wing. Furthermore, I mark each queen before giving her to a nucleus. Marking is much easier with a freshly hatched queen than with a fertile one, not to speak of the greater nervousness in the latter case. This is very important for me because it gives the possibility (when marking the queens differently) of making interesting observations.

As to the temperature of the incubator, I have, as a rule, 90 degrees F.; but it is necessary that the cells be just the same height as the thermometer, because (at least with my incubator) the higher up the thermometer, the higher the temperature.

For each cell I use a little cage consisting of three parts—the wooden cover A, where the cell is fixed with wax, the square wire

tube B and the foot C. The latter is of wood and has two holes which have been well waxed, one for candy, the other for water (w). The water-hole is partly covered by a piece of foundation to avoid the drowning of the queen. In the incubator I put some wet blotting-paper to secure the necessary humidity of the atmosphere. If I have many cells I fill the cage with bees, which may easily be made on an alighting-board, having in one hand A and B (with the cell); in the other, C, on going with the under edge of the wire tube along the board, so catching the bees. In cages with bees I can keep a queen for several days; but it is better not to let her stay longer than one day in the warmth of the incubator, but to put the cage in a dark place at about 60 to 70 degrees F.

The late Dr. Kramer was much opposed to this method of letting the queens hatch in the forbidding, solitary place of a dead incubator. He thought that the sympathy of the surrounding bees in the hive had an influence on the strength and qualities of the young queen. This view is very romantic and poetic, and ought certainly to be adopted with the eggs of hens and geese; but I must confess that I, for my part, have never seen any bad effect on my queens. Most of them show the fine qualities of their parents, and often become four years old, but not older, according to my observations, till to-day. There are beeman, however, who pretend to have had a queen which lived six years. Have any of the readers ever seen a queen older than four years?

Zug, Switzerland.

SOME COMMENTS ON RECENT DISCUSSIONS

BY J. A. BOWEN

So far as I can ascertain the season of 1914 has been the worst ever known in this region, due, I believe, to the cold summer. May and June were like winter. The bees were getting just enough nectar to keep body and soul together. I am wondering whether the season had any thing to do with such a general balling of young queens. In looking for eggs on the thirteenth day I would find the queen in a frantic ball of bees. Some I rescued, many were killed. This freakishness became less evident as the season advanced.

Another feature that caused lots of annoyance was when I took a frame of brood from the center and replaced it with drawn comb or full sheets of foundation. In three or four days, instead of being filled with eggs, as at other seasons, it acted as a division-board. The bees filled it with honey, and on the queenless side started queen-cells. In several instances queen-cells were found in the supers, showing the bees had carried eggs through the excluder.

Many reasons are given why so many young queens fail to return home after

making their nuptial flight. I have tried every plan suggested except hoisting flags of different colors, but all to no purpose. My hives are in rows of pairs, six feet between each pair, and nine feet between the rows. Sometimes from a batch of cells I get nearly all of them mated; at other times not half. The past summer I had three eight-frame hives divided into three parts, each part taking two frames, with entrances facing east, west, and north. Sometimes I could get nine queens from nine cells mated; at other times not more than four or five, all raised, apparently, under the same conditions. On page 324 the editor says that during April at Pompano 90 per cent of the queens are killed by dragon-flies. We have millions of such flies here. The loss of queens may be from the same cause.

On page 345 E. R. Root describes the Marchant scheme for transferring from box hives. Our plan is as follows: Approach the box hive, give it a little smoke; tear a piece off the top, the larger the better; then place the eight or ten frame empty super on top and smoke the bees at the bottom. In a minute or so, up comes the queen. As soon as she is safely on the sides with the mass of bees, lift off the super, put an excluder over the old box, replace the super, and fill it with combs.

That's all. Easy, isn't it? no sawing nor waiting days for the bees to go up when they are ready. They go up when I am ready. In twenty-one days remove the box.

One more proof to that of Mr. Freeborn,

page 723, that bees do discriminate against black. On one occasion a number of angry bees followed me to the house. As I neared the back door, two cats, one black and the other mostly white, lay sleeping on the steps. While I was some feet away the black cat jumped up and made a lightning leap for cover as though in a fit, while the white one just opened its eyes and yawned.

One of the best drinking arrangements for bees I know of is a trough or iron wash-tub. Put in a little sand or soil; throw in a few roots or slips of parrot's feather. In a short time one has a dense growth of one of the daintiest water-plants, and at the same time it gives the bees a chance to get a drink without drowning.

That rain-barrel cistern for the beeyard, page 909, may be ideal for Alabama; but for California it is useless. We don't look for rain from the end of March till the end of October.

A. C. Miller's wire bee-veil, page 810, works well in violent wind storms, of which we get many during the honey-flow; but with the temperature at 110 for weeks I can better endure the stings than the weight of the veil. Coming in from the apiary one day with a severe headache, due to the heavy veil, Mrs. Bowen's mother, a clever woman, took a piece of cheese-cloth, put in a black net in front for the eyes, and round the whole veil sewed a light spring wire about on a line with the lips. I never wore any thing more convenient and sting-proof.

Dixon, Cal.

AN OUTLINE OF HONEY SUCCESS

BY FRED LEININGER

The question is often asked by beginners, "How shall I produce a honey crop—can I make more money on extracted than on comb?" It is not a question to be answered offhand. A number of things must be taken into consideration, and then it will generally be left to the beekeeper to decide for himself.

The fact that there are experienced and successful beekeepers producing extracted honey is pretty clear proof that they find extracted more profitable than comb; but there are also experienced and successful beekeepers who produce only comb. Just as clearly they deem comb more profitable for them.

It may be well to mention some of the items that are factors in the case, other things being equal. Comb honey has a preference because it brings a higher price

—perhaps a half more. On the other hand, it is generally believed that a half more of extracted than comb can be produced, though some say this difference is not so great. The location of the market has something to do with this, since there are localities where a pound of extracted brings nearly if not quite as much as a pound of comb honey. In some regions the nectar-flow is of short duration, but comes in a flood while it lasts; in others the flow is light but long continued. The former is favorable for comb, the latter for extracted.

The beekeeper must to some extent cater to the wishes of his customers. Where the harvest is mostly of dark honey of strong flavor, the preference is for extracted honey. Such honey may be sold for baking purposes while lighter honey is desirable for sections. It requires more skill to

produce comb honey, and more labor in the apiary during harvest. The swarming problem is vastly more troublesome with comb than with extracted honey.

Four essential factors enter into the securing of a crop of honey. First, a sufficient amount of healthy and well-nourished nectar-secreting plants within easy range of the apiary. Second, weather conditions favorable to nectar secretion and bee-flight. Third, a large number of workers in excess of those needed for the work

of the colony. Fourth, colony conditions making the storing instinct dominant.

Every operation of the season should be directed toward securing the greatest possible number of vigorous workers at the proper time.

Let me say that, if the beekeeper follows these simple rules, he will secure a crop of honey which will help to make the old world happier and sweeter.

Fort Jennings, Ohio.

SHERLOCK HOLMES ON A BEE-TRAIL

BY THE AMATEUR

The beekeeper who has never indulged in the pastime of hunting bees has certainly missed one of the most delightful of all outdoor sports. Interest is always keyed up to the highest pitch. There is always the possibility that the bees are in the next tree beyond. When the bee-hunter gets on a "hot trail" darkness alone will cause him to give up the quest.

If the farmer who doesn't feel like going down into his pocket to pay for a few colonies would just go into the woods, hunt them in trees, and get some beeman to help him put them into modern hives, the experience would go a long way toward making his beekeeping a success.

There is no finer outing for a boy than a bee-hunt. If a lad can be encouraged to go into the woods and hunt for himself a colony of bees the persistence and self-reliance which prompt him to follow the hunt to a successful conclusion will go a long way toward making him successful in the care and management of the colony, and, perhaps, will be the first stone on which will be built a future occupation.

Some one may say that it is impossible to find wild bees in his locality. It is very doubtful if there is a square mile of timber, either virgin or cut-over lands, where forest fires have not run recently, that has not one or more bee-trees.

If the bee-hunter can find where bees have been watering on fresh water, and notice their course from there, it should be comparatively easy to find the tree. Still it was under just such circumstances that "Pennsylvania Jake" had his hardest luck.

Not so long ago I became greatly interested in bees and every thing pertaining to them after I had been presented a bee-book. "Langstroth on the Hive and Honeybee"—one that was read and followed by my grandfather. This led to my reading all I

could find on bees. From reading the books I went into the woods, and, with no previous experience, found sixteen bee-trees one summer, and did a boy's work in a lumber-camp besides.

Toward the close of summer, one evening we had word that the railroad could furnish no cars the following day, so that meant "a day in the straw." Pennsylvania Jake came to my door and said, "By gosh, dogs! what are you going to do to-morrow?" Then he told me of a hybrid "bee" that was located about two miles up in the timber somewhere, but that he had been unable to find it, though he had been trying every "day off" all summer, and the year before, too. It was watering on fresh water, and surely it didn't go far; but he said he was sure he had examined every tree for a mile and a half in the direction they flew.

The reader may be sure I speedily consented to go along, for Pennsylvania Jake was the most famous bee-hunter of that locality. He had found unknown scores of bee-trees. A bee-tree he couldn't find was some tree!

In my dreams that night I could see bee-trees everywhere. The night was far too long, but morning came at last. We had breakfast, stuck a lunch in our pockets, and were off. I carried a small box with a hinged cover. In this I placed about a pound of honey. I also had about an ounce of aniseed oil, which I had been told was very good to use in bee-hunting.

Arriving at the small fresh-water spring where the bees had been watering so long, behold, the first bee of the morning came also.

It might be well to state that the spring was located at the edge of the large tract of timber which had been recently slashed and the bark peeled, leaving the hard wood alone standing. This adjoined on an east-and-west

line a very large tract that had been cut over years before. North of the line was the old timber tract cut over at a time when hard wood was almost valueless. Consequently there was a very heavy growth on the old timber tract right down to the spring, while the underbrush had grown up thirty feet high.

The first bee arose and started straight down the edge of the old tract, but on the side recently cut, in a westerly direction. There was an old timber road cut on the edge of the slashing, running parallel with the line, and the bee flew about six feet above the ground along this road. We could see her for an eighth of a mile. We sat down till a few bees came and went. All went in the same direction till about a dozen bees had come and gone. One bee seemed uncertain which way to go, and at last went in the opposite direction. "A mighty good course," said Jake. "Let's go."

Now, I had been thinking mighty rapidly for a boy, and concluded that this bee-tree was not where it seemed to be or Jake would have had it long ago. I noticed that when the bee going in the opposite direction got about six rods away, or just past the heavy timber, it swung around in a northerly course.

"Which way?" I asked.

He looked at me in surprise. "Why, the way the bees are going, of course."

It was then that I explained to him that it was my conviction that the bees were northwest of us. There was a tract of very heavy timber near the spring; and the underbrush being so heavy the bees preferred to fly around the timber to flying over it

when heavily loaded. "I understand that," said Jake; "but them pesky hybrids never go out of their way that far, and you kin hev all the bees you find on that side uv the woods."

Jake hesitated, then said, "Go ahead and try it."

I went back on the line to the spring and waited for another bee to start on the opposite line. I followed it back, saw it curve around the timber, and went right after it. After following through an opening on the east line of the old tract for about a quarter of a mile I came to quite an open place in the timber. Then, looking up, I saw a bee fly through just above my head in a westerly course and almost parallel to the strong line from the spring. I followed till I imagined I must be about forty rods west of the spring and eighty north. Here I began to examine every tree carefully. The underbrush hindered me greatly; but I would look for a small open spot in the timber and look until I saw a bee.

Finally I noticed a loaded bee make a slow half-circle and disappear in the underbrush. I rushed after her, and, pulling back a small birch-tree, saw them going into the body of a big chestnut-tree from both sides in a perfect stream just about thirty feet from the ground. I let out a yell that brought Jake. After looking at them for a while he said, "By gosh, dogs! that's the biggest fool bee I ever saw. They are yours."

That was our first bee-hunt together, but it was by no means our last. I went home happy to think I had beaten one of the most famous bee-hunters in that part of the country.

THE GRAND OLD MAN OF BEEDOM

BY GRACE ALLEN

Four score and more the years have passed, and left him with his bees,
With wonder-working sunlight on the wonder-laden trees;

And life to him has meant not crowds, nor hurry of the town,

But space to see the sky a bit and watch the sun go down,

And time to pause in clover-fields when bees are flashing by,

And will to work, and soul to laugh. (He hath a merry eye!)

Right sturdily and heartily he works with bees and pen,

And through it all he loves his God and all his fellow-men.

Who is this genial man, you ask, of honest-hearted fame,

Whom all the bee-folk of the nation speak about by name,

Who lives in large simplicity of worship, work, and joy?

He's Dr. C. C. Miller, of Marengo, Illinois!

The Grand Old Man of Beedom! He's the Grand Old Man of Beedom!

His life is a happy harmony of worship, work, and joy,

With fun and fame and freedom—he's the Grand Old Man of Beedom,

Our Doctor C. C. Miller, of Marengo, Illinois!

Heads of Grain from Different Fields

The Backlot Buzzer

These city-bred bees soon learn to discriminate. They know there is no nectar in the flowers on a lady's hat, but the grocer says they'd work the combination on his cash-register if there were any honey in it.

Feeding Honey Candied in the Combs

I have a lot of honey sugaring in my brood-comb. What can I do about it? I certainly hate to cut the comb out and throw it all away. Last fall we had a heavy honey-flow in October from what we call frostweed. It is this honey that is mainly turning to sugar. I have several hives with full combs from dead colonies. I wanted to keep these for feeding purposes in the spring. It is all turning to sugar.

Another thing, several colonies have all died, and others are weak. What is the trouble? It is not dysentery. They just gradually die out during winter, and leave hives of honey.

Winston-Salem, N. C.

JAMES NIFONG.

[The frostweed to which you refer is the common fall aster. Honey from this source is causing serious trouble all over the North and East, and is, no doubt, the cause of your bees dying. They probably do not show signs of dysentery with you because they get frequent days when they can fly out, and yet not warm enough to void themselves successfully and get back into the hive. This would cause the dwindling to which you refer.

If you wish simply to save the combs in which the honey is candied, and do not care particularly for the honey, wait until warm weather; uncup them, and hang them in the middle of the brood-nest of your colony. The bees will quickly clean them out. They will, of course, at the same time consume a large part of the honey, but will throw the harder portions out. In case you wish to use them for stimulative feeding in the spring, uncup them and

hang them in the center of the brood-nest as in the above-mentioned plan, and return to the hive every two or three days and remove these combs and dip them in warm water. This will help dissolve and dilute the candied honey, and the bees will remove it and use it. Before placing the combs in the hive they should be marked so that you can readily remove them without disturbing the others.—Ed.]

More Hints on Binding

On page 37 D. W. Howell gives a very good suggestion for binding a file of GLEANINGS with nails. But he tells us to make the bottom edge even. It will be better to make the top edge even, so that it will gather less dust when it stands on the shelf. The bottom edge does not need to be any evenner than it can be made by trimming the extra-long ones with shears. It will be still better security against dust if you have the top edge cut smooth after the volume is fastened together; and if at the same time you can cut the front edge smooth, turning the leaves to find a desired page will be much easier. To cut a block of paper smooth, clamp it as tight as possible in any sort of vise or clamp, and then cut close—not a sixteenth of an inch away, but close—to the line along which the vise holds it. Any thing that will cut will do; but it is much better that the knife be either sharp or driven by a strong power; and even with strong power it is better to have it sharp. That is why the printer, especially if he knows there are nails in the thing, would rather cut the edges for you himself than trust you to handle his cutting-machine.

If you don't have stiff sides, the outside pages will soon get ragged with pushing into place on the shelf. So put on pasteboard sides, holding them on by a cloth back glued to them, or by a cloth that goes over back and sides both. The nails can go through the cloth, or the cloth can be glued on over the nails and hide them; but if you put it over the nails I advise you to see that the very best glue holds it to the pieces of leather that Mr. Howell told you to put under the nail-heads.

Cotton Cushions Effective Protection

We have noticed H. G. Quirin's inquiry on the use of cushions for the protection of the bees, and in reply would state we have been using these for the past eight years, and find they work wonders in protecting the bees both in winter and summer. We use the telescope cover with one of these cushions over the super cover the entire year, and have never had a colony freeze in the winter nor a comb melt down in the summer, although we have had weather below zero.

In this way our bees are protected from any sudden changes in the weather, and we find they build up earlier in the spring and later in the fall when they have this protection.

J. P. MARTINE & SON.

Finds Drones Out Early

While I was in my beeyard on the 11th of February, a fine day, I found to my surprise a number of drones flying out of one of my hives. Evidently it was their first flight. On the 13th I again found drones coming out of that one hive, but none from any of the rest of them. These are the only drones I have seen in this locality. If I had a queen to be mated within the next four or five days I am sure I should have no difficulty.

Wants Plan for Extracting-house

Please give me a good plan for an extracting-house.

Escondido, Cal.

SAM SAKUTT.

[There are many possible arrangements of the fixtures in an extracting-house, and it is hardly possible to recommend any one arrangement that would suit every one. The drawing, however, shows the floor plan of an extracting-room, which is very convenient. This is for a building 12 x 18 feet. A smaller room would answer the purpose almost as well, but the larger building costs so little more that it is economy in the end.]

FLOOR PLAN OF 12 X 18-FT. EXTRACTING-ROOM.

(A) Capping-melter; (B) honey-extractor; (C) honey-pump; (D) tank; (E) engine; (F) bench; (H, I) small opening with wooden doors for passing supers in and out; (J) door; (K, L, M, N) windows.

There should be two shelves at least three feet wide running the entire length of the building, and located on each side above the windows, perhaps seven feet high. These shelves permit the storing away of such articles as are not in use, in order to leave the floor clear for the work at hand.

Remember that there should be no screens at the door. Glass may be used if necessary for light, but the screen should be at the windows only so that there will be no bees bothering about the door during extracting time.—Ed.]

Has Lost No Colonies on Account of Aster Honey

The bees here have been flying a little nearly every day for a week or more. I was afraid they were not going to winter well on the aster honey, as some of them were showing signs of uneasiness and dysentery. I haven't lost any on account of the stores. I lost one from queenlessness. Not over half a dozen colonies in my 80 could be called weak.

I have four nuclei that I wintered in the cellar on aster honey. They are in fine condition. I have them out now.

The bees are carrying in something that looks like brown pollen. They will not touch flour.

BYRON S. HASTINGS.

Brookville, Ind., Feb. 23.

Sweet Clover in Kentucky

It is one of the prettiest sights the eye ever beheld to see from five to ten acres of sweet clover in full bloom, bees coming and going. Our county has always had more or less of sweet clover. It soon restores old waste land, so that in a few years it will raise splendid corn, wheat, and tobacco.

If the writer of the editorial, page 48, Jan. 15, will call on me in June I will show him a sight hard to beat. I will take him through Pendleton and

Robertson counties. The statement that they grow nothing else is, I think, a little strong.

We have white clover, smartweed, and Spanish needle. I do think there is too much tobacco grown in the three counties. Let him come about the middle of August and he can buy sweet-clover seed by the carload.

Brookville, Ky.

L. T. RICE.

Success with Soft Candy

The temperature reached sixty here to-day, Feb. 13, and what a fine flight the bees had! They have come through thus far remarkably well considering the cold weather. A few show symptoms of dysentery. For this reason I made up fifty pounds of soft candy by Dr. Gates' formula, and gave to about that many colonies a pound each. I tried it last spring on ten colonies, and found it remarkably good to cure dysentery and bring them through spring weather in good order. In fact, I believe it saved those I tried it on last spring. For that reason I gave it to more this time, believing it would help them all.

In relation to Straw, p. 95, Jan. 15, I know Dr. Miller's great crops of honey, and his success as a keeper of bees. I desire to sit at his feet and learn; and while I know he has eight-frame hives in his yard I never think of him as an eight-frame-hive user from the testimony I have gathered from himself and those who have visited his apiary. Rather he uses sixteen frames in the two hive-bodies. Many times I have read his reply to the beginner's question, "What size of hive shall I adopt?" He always advises a size larger than an eight-frame, and rather apologizes for using it himself.

Urbana, O.

O. J. JONES.

Home-made Bee-gloves

Without suitable bee-gloves, and not able to get them of the right size, I sewed long wrists with rubber in the top to a pair of common six-cent canvas gloves, then melted some beeswax and soaked them in it. The bees rarely try to sting the wax-coated surface, and it is practically sting-proof, as at the most they can only prick through, not sting to any depth.

The best thing I can do for a bee-sting is to squeeze it until the blood starts. This seems to get the poison out of it. A solution of chinolol removes the soreness for me the best of any thing I have found. If not attended to, stings poison me badly, and this grows worse the oftener I am stung.

Glover, Vt.

JEAN WHITE.

Is Honey Capped Air-tight?

The value of bottled honey as a food might be greatly affected by the knowledge as to whether honey-cappings are absolutely air-tight. Can you give any method by which definite determining tests may have been made?

Ft. Smith, Ark.

L. E. KERR.

[The principal proof that the cappings over honey are not absolutely air-tight lies in the fact that, when comb honey is stored in a damp cool place, the honey absorbs moisture from the air, becomes thin and watery, and oozes through these cappings. If the cappings were air-tight this could not happen.—Ed.]

Ohio Bees Gathering Pollen in February

February '21 our bees were gathering pollen and nectar. The temperature was 52 in the shade. This is the first time in thirty years when bees gathered pollen this early. It is remarkable, considering this cold winter. The bees so far have wintered well.

Lima, Ohio.

MRS. J. A. MOONEY.

A. I. Root

OUR HOMES

Editor

A. I. ROOT A BEEKEEPER.

It sounds a little funny (does it not?) to be told, after I have been fifty years or more before the world as authority on bees, that I am really and truly a *beekeeper*. Well, just now I have *several* "funny" things to mention that are happening down here in "sunny Florida." Yes, and that very expression, "sunny Florida," that you see just now in the advertisements of Florida lands, is about the funniest of them all. Tourists who come down here this winter for the first time ask with a long and solemn face, "Where is your sunny Florida we were led to expect?" etc. Well, this winter is an exception. Things are "sorter turned round." We have not only been having big rains and floods in the winter, but we have (*even here*) "rainy days," sometimes *two* in succession, with "nary a glimpse" of sunshine. "Overhead irrigation?" Bless your heart, *we* have it, and it doesn't cost "nobody" a cent.

Well, my "apiary" that I proudly show to visitors is a little funny, also, for it consists at present of a single three-story hive, and robbers have been so bad *right here* I have hardly dared open it for two months past. Pollen has been coming in, however, more or less, all winter when it hasn't rained. I have sat and watched the bees bring in pollen (heavy loads) with almost as much keen enjoyment as when I used to hold "Blue Eyes" close to the entrance and explain to *her* the "mysteries" of the beehive.* Dear me! Blue Eyes is now a matronly mother of two boys, one of them taller than his mother; and the other just now as intent on studying the heavenly bodies as his mother and I were with the bees, almost fifty years ago. Orange bloom is just coming on now, and the robber bees are, I hope, earning an "honest livelihood."

Here in Bradentown we have recently started a *bee convention*, and there are *several* funny things about this "convention." One is, they hold a session (or did) once a week. Another is, there are often less than a dozen in attendance; and a *third* funny thing is that, in this funny little *weekly* convention we have one of the biggest beekeepers in the world. He reports *3000* colonies, and *53* out-apiaries in Georgia and Florida. See Feb. 1st issue for particulars. We have also one beekeeper in this county who owns and manages about *700* colonies

in something like a dozen apiaries. One of the subjects discussed was how to increase as rapidly as possible down here in Florida, where one has only a few hives to start with. The letter below opens up the subject:

Dear Mr. Root:—In accordance with your suggestion I bought a nucleus last summer. They are fine fellows, and are doing well. This season I want to increase.

Can't you give us some articles in the *Florida Grower* or in *GLEANINGS* especially suited to Florida conditions? I have an idea there are many in Florida who need some help in addition to the A B C and other books.

Clearwater, Fla., Feb. 3.

S. H. EAST.

By way of an answer I will mention how I got my one colony. My neighbor Ault sold me a colony of nice gentle Italians; but before taking them away he removed a frame or two of brood and bees which he placed in another hive on the old stand, thus giving them all the returning bees. This made a very good nucleus, and they soon had a young queen that was successfully mated, even in December. Of course, one would be considerably ahead if he had an extra queen to introduce; but while no honey is coming, the loss of time is no very great thing.

Now, *here* is a "funny thing" that it may be profitable to consider. While Mr. Ault declares he can raise queens and *have them fertilized* all winter long, down here, no one has ever yet, so far as I can learn, offered to furnish young queens all winter long. All through March, April, and May there is always a great call for young queens, and no one has as yet gone into the business of supplying them. If I am mistaken, if he will stand up and speak I will gladly give him a free mention.

The last and perhaps the "*funniest* thing" of all about our "convention" is that a bountiful supply of very nice nuts and candy is placed on the table just before adjournment, and everybody "participates." The convention goes about from house to house, or from apiary to apiary. Our host explained the nuts and candy are to induce busy beekeepers to come. Isn't this really a "funny world," any way, and does it not behoove us all to be neighborly, and "have fun," instead of quarreling and *killing* each other?

EDISON AND HIS RECENT FIRE, ETC.

In view of what I said about Edison in the Dec. 1st *Homes*, our readers may be interested in the following, which I clip

* She was the baby that used to sing out, "Out doors, I do! out doors, I do!" almost as soon as her papa came to sight.

from the Bradentown *Evening Journal*. Perhaps I might add that both Edison and his good wife came from Ohio near our Medina home. He is eight years younger than I, so I have been able to keep pretty close track of him from childhood up.

Speaking of the incidents of the fire, Mrs. Edison said:

"Mr. Edison came back from the fire shortly after midnight. Then he went to his room and busied himself all night with plans for new buildings. At 5 o'clock he decided to go to bed, but in a few minutes was up again.

"He wanted to rush down to the factory and get busy with his men. I begged him not to go down. Then I telephoned to the office and told them to replace to their natural positions all the books and other office belongings which had been removed. I wanted every thing in such condition that it would appear natural when Mr. Edison went to his office. All the time he was insistent upon going down, but I calmed him down and kept him here.

"At 10 o'clock they telephoned from the office that every thing was about straightened out, and for him to come down. But at that time he was all tied up with reports and plans, so I did not tell him. At 1 o'clock he went to sleep. He is up in his room now, and he will not be disturbed for any thing in the world."

It is true that Edison's losses are small in view of his wealth and prestige and power—a mere trifle in comparison with the losses which come to the humble ditch-digger and his family when their humble home goes up in flames and smoke.

But Thomas A. Edison once was a poor working boy. There is inspiration in his life, and attainment for every boy and young man who has a place to achieve in the world.

There should be an inspiration in his life for those who willingly fall into the "has been" class at forty.

Thomas A. Edison is an old man, according to the calendar as the world counts time.

He is not a quitter.

Every little while I say to Mrs. Root, "Sue, here is the kindest and most encouraging word for the Home papers yet;" but the letter below, I verily believe, "caps the climax."

Dear Uncle Amos.—Of course you didn't open this yourself; but I hope the busy helper who *did* will stop reading this right here and send it to you in Florida. I have loved you since I used (away back in 1884) to sit on my father's lap and read GLEANINGS with him. He has long since gone to his reward. The old home is occupied by strangers, and has no orderly beeyard. I was the youngest child of Stephen Luther, whose magazine at that time was directed to Fairview, Erie Co., Pa. Later it was Girard, same county. He always felt sure of goods from "Root's," and enjoyed the whole of GLEANINGS, but especially *Our Homes*. This morning I was looking through an old book of his and found a copy of the description of his device for lowering swarms from treetops by means of a basket and pulley, etc., which you at one time published. Can you imagine the tug at my heart, and how blessed memories came flooding back when I found in the February copy of *Ladies' Home Journal* the advertisement of A. I. Root, etc.?

Your children were near my own age. And just as they were growing up, helping you and getting educated, I was growing up, learning the bee business with father, getting some education, and learning to love to try to serve the heavenly Father. I may be imposing on your good nature by writing all this, but I am choking back the tears which just the line, "*The Home of the Honeybees*" in that adver-

tisement brought. I really feel that you are an old and very dear friend. Father and mother are gone, but I hope you are well and as happy as a true child of God has a right to be. How many years you have been "standing on the promises," and seeing them fulfilled! I am very glad I ever knew you through the "blessed bees." Dr. Miller and Emma, Hutchinson, Doolittle, and many others who wrote in GLEANINGS were familiar to us, but I never got so close to any of them as to you. How often mother's voice broke as she prayed our Father to prosper you for the sake of this work which you were able and eager to do. Father used to wish that you would "wheel" to our place, but you were always so busy that he never dared write an invitation to do so. It is so long since I donned a bee-veil or saw a copy of GLEANINGS that I do not know what the world of beekeepers are doing now.

If you are the same in disposition as when I learned to call you Uncle Amos you may be interested in hearing that one of your early readers is here in the oil region, and the mother of five sturdy youngsters.

I know you would have enjoyed last New Year's day if you could have been in the midst of fourteen girls from my Sunday-school class who spent the day with me.

I wonder if you are as enthusiastic a driver of automobiles now as you were a rider of bicycles years ago. Perhaps you might be tempted to visit Bradford next summer, and drink some of the cold water which comes up 200 feet when oil-wells are driven in this locality. I should be as glad to welcome you to Mapleside (as we call our home) as though you were really and truly my Uncle Amos, as I learned to think of you years ago.

The last copy of your magazine father ever sent me told of the Buttercups you were experimenting with.

MRS. SARA GERTRUDE GREENWOOD.

Bradford, Pa.

A KIND WORD AND SOMETHING MORE FROM AWAY OFF IN MONTANA.

Mr. A. I. Root:—Just a word of kindly appreciation for you for the Home papers. I have never missed reading them for a number of years, and often they are all that I find time to read. They have been a great help to me; and that article, "The Defeat of Injustice," the first one, went into my scrapbook and into my life. I have 50 copies of the booklet, and will use them for free distribution soon in the Sunday-school.

Two years ago while on the Pacific coast I came across the enclosed Lord's prayer, and made a few purchases at the time at 50 cts. (on satin) in the new Times building, and now I have them for free distribution on a limited scale. The Times editions were repeatedly exhausted, and even at 50 cts. I had to place orders ahead for even a few copies. I never tire of reading this composition, and trust that it will be of much pleasure to you.

Corvallis, Mont., Nov. 10. E. H. SHELDON.

THE LORD'S PRAYER, WITH A "READING BETWEEN THE LINES."

The following beautiful composition was captured during the war at Charleston, S. C. It was printed on heavy satin, July 4, 1823. It was picked up by A. P. Green, of Auburn, Ind., at Corinth, Miss., the morning the rebels evacuated it, May 30, 1862.

Thou to the mercies sent our souls dost gather
To do our duty unto thee.....*Our Father,*
To whom all praise, all honor should be given;
For thou art the great God....*Who art in Heaven.*
Thou by thy wisdom rul'st the world's whole frame;
Forever, therefore.....*Hallowed be thy Name;*
Let nevermore delay divide us from
Thy glorious grace, but let.....*Thy Kingdom come,*
Let thy commands opposed be by none,
But thy good pleasure and.....*thy Will be done;*
And let our promptness to obey be even
The very same.....*In Earth as 'tis in Heaven.*
Then for our souls, O Lord, we also pray,
Thou wouldst be pleased to.....*Give us this day*
The food of life, wherewith our souls are fed.
Sufficient raiment and.....*Our daily Bread.*
With every needful thing do thou relieve us,
And, of thy mercy, pity.....*And forgive us*
All our misdeeds for Him whom thou didst please
To make an offering for.....*Our Trespases,*

And for as much, O Lord, as we believe
That thou wilt pardon us.....*As we forgive,*
Let that love teach, wherewith thou dost acquaint us;
To pardon all.....*Those who trespass against us;*
And though, sometimes, thou find'st we have forgot
This love for thee, yet help.....*And lead us not*
Through soul or body's want to desperation,
Nor let earth's gain drive us.....*Into temptation.*
Let not the soul of any true believer
Fail in the time of trial.....*But deliver,*

Yea, save them from the malice of the devil,
And both in life and death keep.....*Us from Evil;*
Thus pray we, Lord, for that of thee, from whom
This may be had.....*For thine is the Kingdom,*
This world is of thy work, its wondrous story
To thee belongs.....*The Power and the Glory,*
And all thy wondrous works have ended never,
But will remain forever and.....*Forever:*
Thus we poor creatures would confess again,
And thus would say eternally.....*Amen.*

HIGH-PRESSURE GARDENING

THE DASHEEN IN CUBA, ETC., FROM ANOTHER
"LONG TIME FRIEND."

Friend Root:—I will now explain what I meant when I said that the dasheen craze got me for about \$40. In the first place I will state that my folks are great on Irish potatoes, and say they cannot live without them; and as they are sometimes hard to get, and poor at that here, I have tried to replace them with any thing and every thing I ever heard of that would grow here. Every thing has failed so far; so when you got to praising the dasheen ("sky high") I thought they would do. To try them I sent \$2 to the Brooksville Development Co., and told them to send me what that money would cover, postage paid by registered mail, as I wanted to try them. In due time I received a letter from them saying that they had sent me a bushel by express for the \$2.00. This was the beginning of June. My son was up north at the time, and I was sick, so I could not go to the station myself; so after allowing a reasonable time I sent a man after them. For some reason they were nearly three weeks on the way, and that man had to make *seven trips* before he finally got them. He charged \$2.00 a trip. That made \$16; the express charges were about \$4.00. This brought them up to \$20, when I finally received them. And what did I get? Just 18 lbs. of dried-up little tubers the size of marbles. There were about 460 tubers in the 18 lbs., so you can judge for yourself what size they were.

I could not believe that any experiment station would send out such stuff. I thought that perhaps some one had changed them, so I wrote to the Brooksville Development Co., sending them a sample, and asked them if that was what they had sent, and also asked them to write me as to how many pounds they had delivered to the express company, etc. They merely made no reply at all.

Well, I threw away the larger part of them, and planted the best about the last of June, not expecting they would do any thing; but in November I dug quite a lot of nice tubers about the size of a hen's egg. The next season I planted these; or, rather, I planted them the last of January, and in July and August I had a splendid stand of them. They beat the picture you had in GLEANINGS of your own. Then in September we had a three-weeks' drouth here, and they all died down to the ground. Along in October they sprouted up again, and in November I dug them, and got about 40 bushels. Now comes the "rub." Nothing would eat them. The family said "once a year" was enough if there was nothing else. Neither cat, dog, rats, chickens, nor pigs would eat them, either raw or boiled. I finally disguised them by boiling and mixing them with cornmeal, and fed them to the pigs in that manner, and so got rid of them.

I want you to understand that I am not blaming you for any failures I may make in following you. Some things have turned out good with me here, and some have failed. Those chufas you wrote about—

heavens! how they bore here! and they were good to eat—a fine nut; but I could eat them faster than I could wash off this Cuba soil from them.

Mulberries have done the best with me. I am getting a fine lot, and the northy berry is the only berry that can hold its own with the grass and weeds in Cuba.

I wanted to try helianti; but you see what Lovett said about it. If it would grow in bushes and be easy to dig I would still try it.

Well, old friend, things have not gone very well with me these last few years ever since the cyclone, and I suppose I am somewhat sour. Cuba is going backward. We don't get the honey crops we used to; and this year we are not getting any thing for our honey on account of the war. When we read of the war there, floods here, earthquakes in Italy, drouth in Cuba in summer, heavy rains in winter, all kinds of crops ruined, it looks as if even God were at war with humanity. The way things go, it makes a fellow feel as though he wanted to run away from himself. I am hoping for better times, however.

Paradero Mangas, Cuba. C. F. HOCHSTEIN.

I believe the above is the first unfavorable report we have had from the dasheen. Let me explain a little. The Development Co. mentioned are in no way connected with the Government Station at Brooksville. The small dasheens are the ones usually sold for seed; and had our good friend H. planted the dried-up ones I think every tuber would have made a plant in time. After filling all orders last May I planted the poorest dried-up ones, and nearly all grew. In regard to their edible qualities, Cuba soil, or the kind of soil used, must be at fault. We are now using them at every meal, and our neighbors agree with us. We boil the skins, or peeling, after scraping out the inside (of the baked dasheen) for the ducks and chickens, and they "go for them" more than for any other feed. Helianti is more trouble to dig and wash than the chufa. Friend H., could not that bright young lady who man-aged the turkeys so skillfully make them take to dasheens?

A GREEN CORN "SCRATCHER."

Mr. Root:—I notice that you inquire if any one knows where you can get a corn-scratcher. I do not know about that instrument, but I have for the past 45 years been in the habit of using a sharp peeling-knife, such as Mrs. Root would use for peel-

ing vegetables, and score down the center of each row of corn, and the tender corn will slip out of that tough hull, which, as you say, is very indigestible. In fact, it used to give me a very uncomfortable feeling like a chunk in the stomach until I adopted the method I enclose. You will find the cob simply covered with the hulls when the corn is of proper age for eating.

I very much enjoy reading all articles in the Home Department, and trust you and Mrs. R. may live many years yet in peace.

MRS. MARY O. HIGGINS.

Southern Pines, N. C., Jan. 18.

A GREEN-CORN SCORER.

According to GLEANINGS of December 1 you wish to know where to get those green-corn scorers. They can be had at John Wanamaker's, in Philadelphia. They cost 15 cts. They certainly are a very fine arrangement to score green corn. If the scorer is drawn lengthwise over the ear of corn before eating, when you go to eating the pressure of one's teeth will cause the kernels to come out nicely and leave the hull on the cob, providing the corn is not too old and hard. It is fine. I do not care to eat corn without the scorer,

Doylestown, Pa., Dec. 18.

A. C. GROSS.

HEALTH NOTES

SOME MORE GOOD HARD "COMMON SENSE"
FROM DR. WILEY.

As you read it, imagine where you hear my "amens!"

TWO KINDS OF CODDLING.

Dr. Harvey W. Wiley, pure-food advocate, has a notion or two outside the field of drug poisoning well worth recording. "To cure a cold," he says, "take a bottle of cough medicine, set it on a table in the patient's room, open all the windows, and throw the bottle through one of them."

"Three-quarters of the children who die," he says further, "are killed by love. Love is the greatest assassin of childhood." Coddling he deprecates as a practice hurtful to the development of boys and girls into healthy, useful manhood and womanhood.

The doctor, doubtless, is speaking primarily of foods and the use of drugs and medicines. But the subject goes much further. Coddling does not necessarily involve the use of either.

There is needed on every hand a better appreciation of the value of hard knocks. A child whose pathway is smoothed through early life has missed a valuable source of training; he has been deprived of the privilege of a discipline which, in all probability, his parents had in full measure, though they may have forgotten it.

It is mistaken kindness to play Montessori to every childish complaint. Call it love, if you will; it is not real love, but an erroneous application of gentleness. In all directions are evidences of the need of a sterner discipline—not an unkind, Spartan-like insistence on the forms of obedience, but a paternal and maternal demand that regulations established for the control of us all shall not be broken down by default of effort to see them maintained.

Coddling is at the bottom of school "strikes." A pupil who knows that the discipline of his teachers will be upheld at home is not likely to lead a "strike" nor follow one far. The boy who makes it unpleasant for his teacher seldom is called to account for making it unpleasant for his mother. In the training of childhood to meet the obligations of a life which knows no Montessori systems, the home and the school must stand together or both will fall.

There are two kinds of coddling. To one impure drugs have no relation. Dr. Wiley is right whether he meant one or both of them.—*Cleveland Plain Dealer.*

INTERNAL BATHING, ETC.

Mr. A. I. Root:—I have become somewhat interested in the claims of Dr. Chas. A. Tyrrell, of New York, in regard to internal bathing. I recall that, several years ago, when I read GLEANINGS regularly, you were an enthusiastic advocate of this system of treatment. Do you find it a good system to tie to, or did it develop bad features after longer trial? Perhaps you have answered these questions in

GLEANINGS; but not having kept bees in recent years, and having many other interests, I have not followed your writings as I once did.

Philadelphia, Pa., Jan. 2.

C. B. THWING.

In my absence Ernest replied as below:

Mr. C. B. Thwing:—My father is in Florida; but I can speak for him on the question you ask—namely, the matter of internal bathing. He does not use it now as much as he formerly did—only in case of an emergency. Both he and myself have found that it is very much better to eat apples or oranges or grapefruit for the evening meal than to depend on the bath to free the colon. I used to depend on it entirely; but my health was not nearly as good as it is now when I depend on nature's way, the eating of acid fruits. Sometimes, when I do not get sufficient flushing of the bowels I eat half a grapefruit or an orange just before going to bed. This will usually produce the desired result without any bad effect—effects such as one gets from the use of a cathartic. During late years A. I. Root has been a great advocate of eating only fruit for the evening meal.

Medina, O., Jan. 11.

E. R. ROOT.

I entirely agree with the above, and would add that, years ago, when I tried assisting nature daily in that way, I found my food was not giving me the strength and endurance it should, for the bowels were emptied before nature had finished her work. I have reasons to believe those who at the present time are advertising apparatus for this purpose are not in accord with the advice of our best doctors.

UP-TO-DATE SURGERY; IS IT A BLESSING TO HUMANITY?

As there has been some discussion in regard to the above, in our pages, I have thought best to give the clipping below from such excellent authority as our good and able friend "Ridgway," of the *Sunday School Times*:

YOUR DOCTOR.—He saved others; himself he can not save (v. 31). Which was exactly true, even though hate said it. This is the law of life for all good men. As I write a splendid physician of great fame and large practice has just died in Philadelphia. He has saved thousands by his skill, but he wore himself out in the doing of it. He could not save himself. He said to me one day, "I performed nineteen operations last week, most of them great ones. I shall get paid for but two." They

found him dead last week upon his office floor just where he dropped. He died there all alone. I said to him one day, "Doctor, don't you ever get callous and hardened to surgical operations by doing so much of it day after day?" Said he, "Ridgway, when you put your loved one, with all the agony of your anxiety, into my hands for life or death, I have in trust the most precious thing on earth. How could I be a man and not feel—how could I get callous and hardened?" And after a moment's silence he grabbed my arm, and said, "Ridgway, week after week with trusts like that I sweat blood." And last week it killed him. And thus good doctors are continually being killed. Take off your hat in reverence to your doctor. And fall on your knees before your Savior (Rev. 12:11).

Please note from the above that surgeons are not, at least not all of them, "hardened" by their occupation; and their fee to those able to pay may not be so very unreasonable after all.

STILL BRIGHT AND WELL AT THE AGE OF 106.

We clip the following from the *Cleveland Plain Dealer* of Oct. 27:

AKRON, O., Oct. 26.—"Be temperate in all things, but work," is the recipe for longevity given by Ohio's oldest citizen, Mr. George W. Austin, Kent, O., who celebrates his 106th birthday today. Two hundred relatives and friends will assemble at the home of Mrs. W. S. Kent to help him celebrate the event.

Mr. Austin was born in Hartford, Ct., Oct. 26, 1808. When 18 months old he accompanied his parents on an overland trip by ox team to Little Rock, Ark., then a wilderness. In 1813 Mr. Austin returned to Kent and has continued to live there ever since.

In 1830 he was appointed a mail-carrier and made regular trips, on foot, between Ravenna and Canton. Mr. Austin has outlived his wife, two children, and three grandchildren. His two brothers died a number of years ago.

This old man is remarkable in many ways. He has never found it necessary to have the services of a physician. He never drank a drop of liquor nor smoked tobacco in any form. It is to total abstinence and hard work that he attributes his long life.

He takes a daily walk of one-half mile from his home to his favorite barber-shop and reads the daily papers. At present he is interested in the suffragist movement, and expresses the hope that he will live to see the State vote dry.

Note, friends, that this man, so well preserved at this great age, never drank a drop of liquor nor used tobacco. Total abstinence and hard work is the way he expresses it; and I am more and more convinced every day of my life that people die because they sit down and give up. They leave the farm and move to town so as to "take things easy," and just as soon as they begin to take things easy, stop exercising, and keep right on eating three meals a day, down they go. As for me, I hope and expect to "die in the harness," God permitting.

CHIEF BY A BEESTING, ETC.

I once took a bad cold, and it settled in my right eye. There were two little white pimple-like lumps that came on the eyeball. They were very painful, and felt just as if I had my eye full of cinders. I

really thought I had, but my wife and others said they could not see any thing except the little white lumps. The pain was simply about all I could endure, and I am not much of a hand to complain either. I had just about made up my mind to go to town and have a doctor, when I happened to notice a nucleus near the house, and decided to look and see if the young queen had begun laying. Possibly I was not as careful as I should have been; but at any rate a bee stung me in the right temple, and in five minutes my eye was so much better that I hardly noticed it any more, and by evening it was entirely well, and hasn't given me any trouble since.

Uniontown, Ala., Aug. 12. L. A. HARGREAVES.

My good friend, your letter reminds me of something that happened a few weeks ago. When I awoke in the morning one of my eyes felt bad; but the more I washed it the worse it became. Finally the pain became, as you describe it, so great that I sent for a doctor. I told him I had gotten something in my eye. A careful search, however, revealed nothing or next to nothing; and after removing every thing he could discover he applied a drop or two of a solution of boracic acid, and the pain and irritation disappeared as if by magic. In fact, I uttered an exclamation of joy and relief to have it disappear so suddenly; and others have informed me that this is the remedy in common use, and affords relief from almost any kind of irritation or similar troubles of the eye. We now keep some of the solution in the house, but my eye has never troubled me since in the same way. Is it not possible that the beesting produced a flow of tears and lubricated the irritating eruption?

KEEPING THE HANDS CLEAN.

When I was in the watch-repairing business years ago it was absolutely necessary for me to keep my hands dry and clean. In handling the delicate machinery of a watch, soiled or perspiring hands could never be tolerated an instant. On this account I always had a wash-basin, with soap and towel, near my work. And this fashion has followed me more or less all my life. Down in Florida I have soap, basin, and towel outdoors near the garden. It saves my climbing the steps to get into the house, saves me from using the towels indoors when I am in a hurry, etc. As Mrs. Root does all the washing, I try to avoid using the regular towel when I am in too much of a hurry to wash my hands *thoroughly*. The white cotton cloth used for sacks for middlings makes a very good towel to be used on such occasions. It is also handy to have around automobiles when you want to wipe your fingers. Down in Florida there is no market for paper-rags, as paper-mills are so remote; and I believe there is no market for grain-sacks or sacks of any kind. They are just

dumped around and allowed to rot after the grain is emptied out. If they were saved up till we get a carload it would pay to ship them; but nobody, at least around Bradentown, has as yet undertaken the job.

Well, now, to get back to this matter of keeping the hands clean. Huber has just made an invention. Those of you who have worked with automobiles know what a task it is to get the black grease off the hands when you once get them badly soiled. Why, it often takes more time to clean up than to do the work. To help matters, I have kept a little dish of sand close by the wash-basin. The sand helps very much to get off the sticky grease. Well, Huber's invention is this: *Before* you go to work at the automobile, or any other greasy machinery, coat your hands with soap and let it dry on. This will not hinder you at all in your work; and when you come to wash, the grease from the dirty ironwork comes

off in an instant because the soap prevents it from getting down into the pores of the skin. Mrs. Root adds a supplement to Huber's invention. She said she read in some woman's magazine that you should "claw" into a bar of yellow soap so as to fill the finger-nails before you attempt dirty work. When you are through, a nail-brush will wash off the soap very readily without a great lot of scouring.

Now, clean hands are not only an indication of respectability, but it lets people know you are careful about making your wife trouble by going into the house and handling things with dirty fingers. I might say something about dirty feet as well, but I have not time just now. Let us all strive, good friends, to have not only clean hands and clean feet, but a clean heart, void of offense toward God and our fellow-man, and the good wife, last of all, but by no manner of means least.

TEMPERANCE

"PHILADELPHIA DRY IN 1916."

Our good friend B. B. Jones (Lake Roland, Md.), keeps us posted about Billy Sunday by sending us clippings from the daily *Baltimore Sun*. Here is one of them:

PHILADELPHIA, Jan. 31.—Making a solemn vow that, when they got the chance to vote Philadelphia "dry," they would do it, 40,000 Philadelphia voters cheered Billy Sunday to-day when he preached his famous "booze" sermon.

They leaped to their feet as they registered that vow, and then swarmed down the sawdust aisles, struggling to get to the evangelist. Failing that, they climbed on the pine benches, and, hurling their hats in the air, yelled the prediction: "Philadelphia dry in 1916."

That was the climax of the most sensational sermon Sunday has preached here. He preached it twice, and 1266 persons "hit the trail" at the two services.

The evangelist scored the farmer who sold his grain to the distillery; scored the man on his way "to church and heaven" who was really going "straight to hell" because he voted for rum; scored those responsible, through liquor, for the asylums, almshouses, penitentiaries, electric chairs, and the 865,000 "whisky-orphaned" children in America.

The words of Lincoln, McKinley, and Roosevelt against liquor were quoted by the evangelist, and deafening cheers rang in the low-roofed building when Sunday grabbed an American flag, crying: "Every plot to overthrow the United States and trample under foot this glorious flag wriggled and crawled out of the pit of hell. That hell was a liquor-hell."

Sunday told of the farmer getting 50 cents for a bushel of corn from which the brewer made 36 pints. With three of those pints Sunday declared eight lives were wrecked, and three persons were sent to the gallows. He stated what the Federal pure-food laws required beer to be made of, and then gave his version of what it really was made of, and he hit at the administration that "kicked out old Doc Wiley, the best friend the American people ever had."

I am beginning to have faith that Mr. Sunday will (God sustaining and sparing him) not only make the *whole United States dry*, but that he alone will ultimately end the war in Europe through Christ Jesus, whose representative and "ambassador" he is—"ambassador to be, from realms beyond the sea."

QUESTIONS IN JUDGMENT.

John O. Keeler was hanged the other day at Clearfield, Ind., because in a drunken frenzy he murdered Joseph Roessner, the Clearfield brewer.

What Keeler has told his God is not known; but this is what he wrote to Rev. Dr. Reeve a few days before he was strangled to death by the law:

I can say with a clear mind that I was never sober from the time I went to work at the Clearfield brewery. I was full of booze all the time, counting Sunday with it, because I had a keg at home on Sunday, and I did not have to get drunk to do what I did. I am here for the murder of Joseph Roessner, but I don't know if I killed him. I can't say. If I could I should be glad to tell the public so, because he made the booze and he gave it to me free of charge, that made me a drunkard and a murderer. It was Mr. Roessner's own product that murdered him and made me a murderer. It was his beer that put my family in distress and lots of other families besides mine.

I began my downward career at a saloon bar and wound up at the Clearfield brewery. I will appear at another bar, the judgment bar of God, and there your Honorable Judge Smith and some of his lawyers, and Joseph Roessner, and a good many more, will appear with me and will be rightly judged.—*Westerville New Republic*.

"HOLDING THE FORT"

Mr. Root:—You will be glad to know that Van Wert has voted dry by 300 majority. We hope that our town will follow the lead of the county seat.

Convoy, O., Jan. 9.

WIVES!! Could you run a farm if your husband's health failed??

Mrs. Hattie B. Hardman of Kenka Lake, N. Y. did. She writes: "My husband's health was poor, and the doctors told him he must be on a farm. He said we would buy a farm if I could run it. I replied that I had not been reading the Farm Journal all these years for nothing, and that I certainly *could* run a farm. So we bought 'Willowhurst' on Lake Kenka, and for two years I have had full charge of everything, and have made a success of it. How much I owe to your little paper I can never tell you. It certainly has done a great deal for me. My husband calls me his 'Farm Journal farmer.'" You can get the Farm Journal as Mrs. Hardman did, 5 years for \$1. Subscription price for unfilled period back any time not satisfied. The favorite in every state. Subscribe now.

EDITORIALS

WE have the largest and most complete exhibit we ever installed, at the Panama-California exposition, San Diego. Look for the big white front in the "Varied Industries" building. We have another (but smaller) exhibit at the San Francisco exposition in connection with the State Beekeepers' Association. Call and make yourself known.

Foul-brood Bill Introduced to Washington Legislature

THE beekeepers of the state of Washington have been successful in introducing to the senate a new foul-brood bill which is expected to pass both houses. In some respects the bill is not what was wanted, but it will at least serve to pave the way for something better two years hence.

The Foul-brood Situation in San Jose

WE visited San Jose on Tuesday, March 9, and are happy to announce that the foul-brood situation there is much better. The inspector, Mr. L. R. Cody, reports that conditions are improving materially, and he has already given a clean bill of health to a number of beekeepers. So far as we can ascertain, there have been no bee diseases except in the immediate vicinity of San Jose. All the beekeepers there are working hard to eliminate it, and before this reaches our readers there will probably not be a cell of foul brood in the vicinity.

The Pennsylvania \$50,000 Bill

PENNSYLVANIA beekeepers will be interested in the following just received from Prof. H. A. Surface:

A bill providing an appropriation of \$50,000, "to be used exclusively in eradicating, controlling, and

preventing diseases of bees, and in enforcing the laws of Pennsylvania relative thereto," has been introduced as House Bill No. 733 by Mr. Jack, of Armstrong County, and has been referred to the Committee on Appropriations; and in the Senate as Senate Bill No. 281. The members of this committee are as follows:

Woodward, Allegheny Co.; Cox, Philadelphia Co.; Curry, Philadelphia Co.; Gans, Philadelphia Co.; Steedle, Allegheny Co.; Kaiser, Allegheny Co.; Aron, Philadelphia Co.; Eby, Perry Co.; Walton, Lawrence Co.; Wood, Indiana Co.; Neville, Montgomery Co.; Sinclair, Fayette Co.; Scott, Center Co.; Rininger, Blair Co.; Thomas, Luzerne Co.; Greenwood, Chester Co.; Jones, E. E., Susquehanna Co.; Lindsey, Warren Co.; Flynn, Elk Co.; Body, Berks Co.; Murphy, Luzerne Co.; Ehrhardt, Lackawanna Co.; Hess, Lancaster Co.; Geary, Allegheny Co.; Conner, Philadelphia Co.; Ramsey, Delaware Co.; Myers, Washington Co.; Walter, Franklin Co.; Goldsmith, Westmoreland Co.; McCaig, Allegheny Co.; Schaeffer, Schuylkill Co.; McClintock, Philadelphia Co.; Fruit, Mercer Co.; Neider, Philadelphia Co.; Bovee, Erie Co.; Shaaber, Berks Co.; Spangler, York Co.; Williams, Tioga Co.; Perry, Philadelphia Co.; Shaffer, Columbia Co.; Kitts, Erie Co.

As President of your State Beekeepers' Association, and member of the Legislative Committee, I recommend you to do all that is possible to bring influence to bear on these gentlemen for favorable action on this important measure.

Beekeepers of the Southwest, Take Notice

THE Southern Conference for Education and Industry will hold its annual meeting at Chattanooga, Tennessee, on April 27-30. In connection with this conference there will be a number of smaller conferences on various subjects of interest in the South. One of these will be on beekeeping. The general meetings are held in the morning and evening, and the smaller conferences in the afternoons.

In connection with the beekeeping meetings, it is proposed to devote the first afternoon to a discussion with farm demonstrators and teachers. The second and third afternoons (April 28-29) will be devoted to a beekeepers' conference to which all beekeepers are cordially invited. A number of prominent southern beekeepers will be

present, and these meetings promise to be most helpful. As soon as a definite program can be announced a copy will be sent. In the mornings previous to the meetings of the general conference there will be a two-hour question-box meeting.

It is hoped that some instructive exhibits can be arranged as well as some practical demonstrations. A room has been assigned to the beekeepers' conference for this purpose. Program in next issue.

The Foul-brood Bill in Idaho Vetoed by Governor Alexander

HOUSE BILL No. 54, by York, was vetoed by Governor Alexander, the reform Governor of Idaho. Mr. Alexander, in his pre-campaign speeches, promised the tax-payers that, if elected, he would save them one million dollars in taxes. The foul-brood bill would require \$5000 to put it into execution. Near the close of the legislature the Governor gave notice that he would veto a large number of bills calling for various appropriations. While he tentatively had promised to support the York bill, he gave as a reason for vetoing it that it provided for an unlimited number of inspectors at \$5 per day, such inspectors to be named by the State Beekeepers' Association. He forgot, however, that the appropriation of \$5000 would have held the limit down to a reasonable number.

We give the Governor credit for standing back of and putting through the most magnificent temperance law for statewide prohibition that was ever enacted by any legislature. G. W. York, formerly editor of the *American Bee Journal*, and a member of the House, was a very important figure in the enactment of this legislation. We will give further particulars later through these columns.

The Bees at the Dismal Swamp

WHEN Mr. Rea was at the Dismal Swamp during the latter part of February, farmers were planting potatoes. The bees were flying every day, and bringing in pollen and even nectar. Some of the queens had six or seven combs of brood. On his return, Mr. Pritchard started for the swamp to begin the active work of building up the colonies, etc. However, to our great surprise, the weather suddenly turned cold, and on March 18 Mr. Pritchard wrote that there had been only half a day when it was warm enough to work with the bees. There had been four inches of snow and much freezing weather. The residents say it is the coldest spring in

30 years. It has been so cold part of the time that the men have been unable to nail up hives in the barn. The United States weather maps show that unusual cold weather has extended well down into the extreme southern states. Even in northern Florida temperatures around 40 degrees have been common. C. H. Clute, of Palmetto, Florida, is our authority for the statement that the citrus bloom in the state will be less than half what is considered normal, and that bees have consumed about double the usual amount of stores. Mr. Clute says that February and March were the wettest and coldest of any year on record.

We are afraid that all that brood so well under way in February will be lost. In fact, when Mr. Pritchard wrote, March 18, he said the colonies were decreasing rather than increasing in strength.

Iowa Beekeepers, Write your Senators and Representatives

The following letter explains itself. It arrived just too late for insertion in our March 15th issue.

There is now in the Agricultural Committee in the Senate a bill establishing a Department of Bee Culture at the Iowa State College, at Ames, to teach beekeeping, to do experimental work, to publish bulletins, etc. This bill, thanks to our tried and true friend Henry Brady, of Dallas Co., passed the House some time ago.

Three more bills of interest to beekeepers have just been introduced in the House. One aims to amend the present inspection law, which states that the inspector, upon written notice from three beekeepers in a given locality, must inspect bees in that territory, and also requires him to return later and make a reinspection of all infected colonies. The amendment would require the inspector to examine bees in any locality upon notice from any beekeeper in that territory, and would leave the reinspection optional with the inspector. If he feels that the owner of the diseased colonies is competent to, and will, give them proper treatment, he will not be required to return to the apiary, but can spend that time inspecting other bees.

Another bill would establish the office of county inspector of bees to be chosen from among the resident beekeepers upon petition to the board of supervisors by ten or more resident beekeepers, or upon recommendation of the State Inspector. This county inspector would receive a salary of \$3.00 per day for time spent inspecting bees, the salary for any one season not to exceed \$75.00, and would be directly accountable to the State Inspector.

The third bill, the one which will probably meet with the greatest opposition, would prohibit the spraying of fruit-trees while in full bloom. The state of Washington compels spraying at a certain time; and if a fruit-grower fails to spray at that time men are sent around to do it for him, and he must pay a heavy penalty. The law in Washington prohibiting spraying fruit when in full bloom is just as stringent. Fruit-men are of one accord in condemning spraying when in bloom; but there is some difficulty in getting some to spray under any circumstances, and it is the sense of some that such a law would deter a few from spraying at all.

Considerable injury has been done to bees in various parts of the state by injudicious spraying; and those who have suffered loss therefrom should make it a special point to write their senator and representative, stating the facts in the case, and also write Wesley Green, State House, Des Moines, naming the parties who do such spraying.

Now, in order to get these bills passed, every beekeeper should address a letter to his senator and his representatives, asking their support of the above bills, and one to the Agricultural Committee members, asking them to report favorably on the first-mentioned bill. The members of the committee are Senator Allen, Arney, Hammar, Fleck, Foskett, Durr, Eversmeyer, Perkins, Fellows, Farr, Lindley, Balkema, Nye, Savage, Grant, White of Iowa Co., and White of Benton Co., and Senator Doran, who is chairman of the committee.

Do not put this off until another day when it is a little more convenient. We must not let these bills die in committee. In order to get them through, every beekeeper should act immediately, and should not stop short of six letters. They need not be long, but tell them what you want, and do it at once.

Des Moines, Ia.

F. C. SCRANTON.

How our Bees have Wintered

To date very few days have been warm enough for bees to fly. We have observed for nearly two weeks that the bees in the warehouse cellar showed signs of dysentery—at times getting quite uneasy. Yesterday morning, March 19, the sun came out bright. We hustled the bees out with the auto truck and team to our basswood yard, where most of them belong. They flew, and cleaned up in fine shape. Although but one colony had died outright, many were needing a flight badly, and were evidently put out just in time. A few days longer in the cellar would have meant disaster. The condition was due, undoubtedly, to aster-honey stores. We are fearful that these colonies will dwindle badly unless the weather from now on is very favorable.

Our queen-breeder, Mr. Pritchard, had some colonies in the same cellar that had been fed sugar syrup last fall, and these showed up in much better shape.

Bees in the machine-shop cellar are quiet and contented since the cleansing flight which they had on February 20.

Spring is advancing slowly—in fact, so far there has not been a single day fit to open hives and examine the bees excepting to lift covers and look for stores and size of cluster. Colonies in the big winter cases and Buckeye chaff hives are just about as previously reported, with brood-rearing progressing slowly. In the end this may be all for the best, as slow gains usually mean sure gains in brood-rearing. We are always apprehensive of a spring that gives too warm weather in March, and then turns cold later. Heavy losses of brood are almost sure to result.

As we have often pointed out, there are many differences in conditions only a few miles apart. In this connection the following letter from A. C. Ames will explain itself. Mr. Ames' bees are not much over fifteen miles in a direct line from the apiary that we are wintering in the large quadruple cases.

Dear Mr. Root:—I have just read your editorial in the March 1st issue in regard to the large cases. It seems very strange to me that you did not find brood. I examined the brood-nest the same day you did, and found brood in all stages from eggs to young bees. I examined six colonies, and found only one colony that did not have sealed brood, and in three colonies I found young bees. I have never had bees winter in a more perfect condition. Of course we have March to deal with, and sometimes it is the hardest month; but as we have had several good fly days I do not fear the result.

It is quite cold to-day (March 9); but the bees are carrying water. When we consider these good results we must also take into consideration that this has been one of the best winters we have had for years—good steady winter weather without much if any wind. Wind is the worst thing we have to contend with in winter.

I believe bees will winter well in all the northern states.

Peninsula, Ohio, March 9.

A. C. AMES.

An Interview with Dr. A. J. Cook, of California, on the Spraying of Cover Crops

WE had an interesting interview with Dr. A. J. Cook, Horticultural Commissioner of California, who is located at Sacramento. In referring to the sprays that were falling upon the cover crops of western Colorado, and which, it was believed, were killing bees in a wholesale way, he gave it as his opinion that these spraying liquids would kill the bees in large numbers. There had been several experiences of that kind in California. He was recommending the vetches, which do not come into bloom when the sprays are applied. In fact, he doubted if it were necessary for the Colorado fruit-growers to spray as often as they were doing. If the work were *properly* done it would hardly be necessary, he thought, to spray when the cover crops of clover were in bloom.

He admitted that the very dry climate of Colorado might call for more sprayings than were found necessary in California, but he thought if the fruitmen and beemen would get together they could easily arrange the matter so there would be no loss to any one.

Cover crops are being used throughout the western orchards to a very great extent, both to supply nitrogen to the soil and to keep it from drying out too quickly. When

plowed under they furnish a fine humus, so necessary to the proper fruitage of the trees.

Dr. Cook went on to explain that the vetches and annual yellow sweet clover, known as *Melilotus indica*, are being used almost exclusively in California for the purpose. In this connection it is proper to remember that *Melilotus indica* is also known as the annual yellow sweet clover. This is also a honey-plant, but not quite the equal of the *Melilotus officinalis*, nor yet quite the equal of the white sweet clover, *Melilotus alba*; but the fact that the annual yellow sweet clover, *Melilotus indica*, is one of the best cover crops that can be used by the orchardist, suggests that perhaps the Colorado fruit-growers on the western slope could use it; if not that, they could use the vetches, both of them supplying nitrogen to the soil, and at the same time make an excellent humus. The beekeepers of Colorado should suggest that their friends the fruit-growers try something else as a cover crop that will not be prejudicial to the interest of the beekeeper.

Beekeeping in the Great West

THERE are certainly some very fine bee locations in the great West. Most of them have already been taken up, and many of them are overstocked. There are localities where new irrigation schemes are under way, and alfalfa is just being grown. These will be found in parts of Montana, Wyoming, and northern Idaho. Most of the good bee territory in southern Idaho has already been taken, much of which is overstocked. About all one can do in established territory is to buy out some good beekeeper. The same rule practically holds in Colorado, Utah, Nevada, and southern California. There is some new territory not taken in the northern part of the state. If any one from the East desires to go into beekeeping he should buy a ticket, and tour the country thoroughly before he decides to locate. In most cases he will have to buy out some one else already on the ground, and probably this can be done.

It certainly does not pay a tenderfoot to go out into the western country and attempt to squat his bees down near some resident beekeeper who thoroughly knows the locality. The newcomer is generally frozen out if it is a freeze-out game.

This is not written to discourage the emigration of eastern people; but it is only fair that they know what they will run up against in old established territory if they attempt to locate without buying out a bee

range. There seems to be a sort of unwritten law among the western producers to stand together and protect each other, and we cannot blame them.

Our Cover Picture

IN this special Quinby number we are much pleased to be able to present so interesting an array of pictures closely associated with Moses Quinby. His son-in-law, Lyman C. Root, whose article appears on another page, made a trip, at considerable inconvenience to himself, to the old home in Greene County, where Mr. Quinby wrote his first book, and where he made most of the investigations which have so greatly influenced the whole beekeeping world. We are especially glad that he secured a photograph of the old mill where Mr. Quinby earned the support of his family in his early years, and where he made his hives. This picture is shown on our cover. The building shown is not the old mill. Some of the old timbers of the latter are to be seen in front of the building, by the rocks that were part of the old dam.

On another page is shown a copy of the old engraving, taken from his book published in 1865, showing queen, drone, and workers, also worker and drone cells. Even with the advanced knowledge gained in the fifty years that have elapsed, this can be considered a most faithful and perfect drawing. In this connection it is interesting to note that Mr. Quinby's daughter made the sketch with a pencil. As Mr. L. C. Root says, it certainly illustrates Mr. Quinby's accuracy in whatever he undertook.

Just as we go to press we received the following from L. C. Root, which is so interesting we give it a place here. The photograph of the extractor will appear in our next issue.

I have secured a picture of the first metal-can extractor that Mr. Quinby made after the one I described.

I am looking forward for the Quinby number of GLEANINGS with much interest. Was he not first to keep bees in large numbers in out-apiaries? first to ship honey in large quantities to any market? first to place beekeeping on a commercial basis with other branches of agriculture? first to use the honey-extractor to produce honey by the ton? first to invent a self-spacing frame? first to discover that when bees are wintering well, they discharge their feces in the dry state?

I have never appreciated father Quinby's life-work as I have since I have been visiting the different places where he spent his life. Everywhere I have found evidences of his unselfish life and largeness of purpose. I am just beginning to appreciate some of the embarrassments he had to meet through lack of appreciation.

You will see why the coming number will be of deep interest to me.

Stamford, Ct., March 8.

L. C. Root.

Dr. C. C. Miller

STRAY STRAWS

Marengo, Ill.

W. J. WOOLLEY, p. 233, reports an average of 30 lbs. per colony. Looks a little like small potatoes. But when you figure it at 18 cents (9d) per pound, or \$5.40 per colony, some of us might be glad to swap places.

I'M PROUD of my native state, good old Pennsylvania, to think she has a governor who would propose \$50,000 for the benefit of beekeepers, p. 216. But then it's just like Governor Brumbaugh. Do you know that he's one of the leading Sunday-school men of the land?

OUGHT not that statement, p. 240, that the building of queen-cells is inseparably connected with swarming, be cut just about in two? Remember that under natural conditions *every* queen, when she closes her career, has cells built for a successor, with no thought of swarming.

G. M. DOOLITTLE, p. 224, my record-book does get daubed with honey and glue, but with a new book each year the trouble is not serious. I don't understand the wind blowing your book open at the wrong place in spite of best endeavors. No trouble worth mentioning here. Locality?

E. S. MILES has covered the ground as to taking bees out of cellar exceptionally well, p. 232. One thing just a little different here. With a two-inch space under bottom-bars, we can quickly clean out dead bees after a hive is placed on its stand, and close the entrance before bees wake up to fly out.

YOUNG fellow, read carefully all that's said, pages 133 and 135, about just exactly how you're to make candy to feed your bees, and then make up your mind decidedly that only in extremities will you ever put any of it in practice, but plan ahead to have extra frames of sealed honey to meet all emergencies. Take it from me, you'll never be sorry.

A GOOD deal is told about sugar, p. 214, and what of it? Well, several things, and chiefly that 86.85 pounds average annual consumption. Do you realize what that means? It means that inverting so large an amount as that is too heavy a strain on the digestive organs, hence a weaker nation. It means something worse than that. For that *average* means that, while some use much less, others may use double that amount, hence a lot of people are practically killed by sugar-eating. Uncle Sam

might do a good deal worse than to spend a few thousands in a campaign to educate the people so that at least half the sugar should be replaced by honey. But in that case could the demand be supplied?

UNCLE JOE BLUNK, referring to my wintering, says I can keep the door of my beecellar closed all the time if I connect a pipe in the beecellar with the furnace chimney, as "enough fresh air will seep in through the walls of the cellar to feed the place." I should have explained that I have a stove-pipe-hole entering a chimney in the beecellar. But no "seep" business is good enough for my bees. They like the air to come in a flood.

"BESIDES there are many basswoods and linden trees," p. 185—which reminds me. Years ago a man in Marengo had in his yard several basswoods perhaps 40 years old. Happening in that part of town one day I noticed that they were taken down, and that some little trees four or five feet high had been planted. With some degree of pride he said, "I had those common basswoods taken out, and got from the nursery some choice shade-trees—lindens."

SURPRISING is that statement, p. 242, that by using the Alexander plan, "putting the queenless colony right on-top with nothing but the honey-board between the chances are that the swarming tendency would very rapidly develop into a mania." Surely so good a beekeeper as Mr. Alexander would have discovered if that were so. Moreover, I have practiced it hundreds of times where cells had been started, and have always counted it a cure for the swarming mania. What can make the difference?

POUNDING home the truth that bees are necessary for pollination, and that spraying in bloom hurts the fruit, will do some good; but no matter how intelligent a fruit-grower is, he will spray before bloom is gone if he is selfish enough unless the law prevents him. He says, "I know all about what you say; but I can't get through spraying in time unless I begin before all have gone out of bloom. Even if I could I don't want to. If I wait till all bloom is over, there is a little danger that some of the oldest fruit will be wormy. If I spray when two-thirds of the bloom has fallen, and kill all yet in bloom, there will still be left more fruit than the trees can mature, and I'll have no wormy fruit. Me for the earlier spraying." Now what reply have you?

NOTES FROM CANADA

J. L. Byer, Markham, Ontario

From numerous reports in late issues of the *Journal*, as well as in private letters to hand, I might be doing a bit of worrying about that yard up north which I have not seen since early in November, and which is wintering mainly on aster stores. Many are reporting bad results in localities further south, where the bees have had a cleansing flight. There are 250 colonies in the yard in question; and as there is no practical beekeeper right near the bees to report conditions to me, I have not the slightest idea how they are. I had purposed to go up before this; but as the distance is nearly 100 miles from my home, and nothing except gratifying my curiosity would be accomplished by the trip at present, I have delayed going. I expect to go there when the first warm spell comes along, and will then report just how things are for the benefit of the many who have made inquiries.

* * *

It is not often that the editor gives me such an opening as that on page 176, March 1, when he tells of so many colonies being dead. He says, "We found the clusters actually starved to death with plenty of stores within two combs distance, either on one or both sides, because the weather remained cold so continuously." It is easy to explain the cause of this loss. There was too much "winter nest." But, joking aside, this is an illustration to prove the necessity of having combs well filled to be sure of successful wintering outdoors in a climate as cold as here in Ontario—much colder, by the way, than it is in Ohio. It is because we have learned this fact by dear experience that I would not be afraid to wager a good deal that, among hundreds of colonies being wintered outside by Sibbald and others, none will be found in the condition so well described by the editor. Bees seemingly can move upward on stores, no matter how cold the weather is; but with steady cold weather they cannot break cluster and move sidewise.

* * *

April is the month in our latitude when beginners often do harm to colonies by handling them too often, many times in unreasonable weather. As a matter of fact, beginners are not the only ones who make these mistakes. Generally speaking, if one has the bees well protected, knows they have

sufficient stores, etc., a let-alone policy is the best by all means. Possibly there may be a very few exceptions, but they simply prove the rule. Hundreds of good queens are lost every spring by the colonies being manipulated too early or at least too often. At this time of the year, for some reason, the bees are unduly solicitous as to the queen's safety, and often on the slightest disturbance they will ball her—something that spells disaster for the colony at this early date. I know it is very tempting on a nice warm day in early spring to have a look to see how that favorite queen is doing—to see how many combs of brood the colony has, and to see the fresh pollen; but better curb your curiosity till a later date than to find, a few days later, when again examining the brood-nest, that some stubby queen-cells are started, telling you that the queen you were anxious about has disappeared.

* * *

On page 180, March 1, P. C. Chadwick says the writer of these notes "complains" because the bees have had no flight since the last of October. I hasten to say that is not quite correct—at least I hardly meant it that way, even if what I said does sound somewhat like a complaint. It is my honest opinion that the man who is keeping bees for a living will either develop the virtue of patience or else become a confirmed grouch; and while I am not any too patient at best, still I hope that I do not qualify under the latter heading. I try not to complain about things I am not responsible for or have no control over—the weather comes under this list; and if I wish to complain, there is always enough material to draw from in connection with things I am responsible for.

P. C. Chadwick's bees may have too many flights to suit him during the winter season—if we can term any part of the year in California under that heading; but when I say that at this date—March 8—our bees have not yet had a flight, I venture to say that he would sooner choose conditions as they are with him than to change with us. However, we are doing no worrying; and if the bees have had no flight, we have had a delightful winter, and the chances are that we shall have enough bees left for "seed" anyway. A few weeks at the most, and we shall know the worst or the best as the case may be.

BEEKEEPING AMONG THE ROCKIES

Wesley Foster, Boulder, Colorado.

CAUSE OF AMERICAN FOUL BROOD.

Mr. J. D. Bixby has a rather amusing and somewhat interesting paragraph in the February *Western Honey Bee*. He says he does not know what are the causes of American foul brood. Then he proceeds to guess or presume that there are two kinds of cases of American foul brood—contagious cases and sporadic cases. He says (or I guess he does) that rotting drone brood from a healthy hive will, if the bees work over the stuff and take up the "foul juices," produce "sporadically" American foul brood. You are to understand that this is not genuine contagious or infectious American foul brood, but just sporadic American foul brood which means that it may be carried to other hives or it may not. I'll bet the price of half a round-trip ticket from Boulder to Covina, Calif., that Mr. Bixby cannot produce a case of American foul brood by using any such method. I do not care whether it is "sporadic" or "contagious" American foul brood.

The bill before the Colorado legislature, Senate Bill No. 77, introduced by Senator Schermerhorn, is in the hands of the Finance Committee, of which Senator Hasty is chairman. This bill is the one designed to control the cutting of cover crops before orchards are sprayed. There is some opposition to this bill among some of the fruit-growers, but it is probable that the bill can be passed if the fruit-growers understand it. It is not designed to force the fruit-growers to practice clean cultivation, as has been claimed. The object of the bill is to prevent the spraying of orchards when the cover crops growing therein are in bloom. Cutting the blooming clover, or turning it under just before doing the spraying, will solve the difficulty, and this phase of the situation is the only one touched.

If the beekeepers in the fruit districts are not given protection, such as is designed in this bill, there is no use in trying to carry on beekeeping for honey production in the same district with fruit-growing.

If all Colorado beekeepers will write their representatives in the legislature at once, the probabilities are that the bill may be passed. Write at once, and keep on writing until you get a definite pledge from your representatives that they will support this bill. If you can see your representatives personally, so much the better. Telegrams

also often have a very beneficial effect. We have used them to good effect in the past, and they will be used in this campaign.

Frank Hill, in March 6th issue of *The Country Gentleman*, has a very interesting article on "A One-horse Farm." He is apparently located near Kansas City, and has a 5½-acre place from which his income is around \$1400 a year. His bees bring him in \$500 a year on the average, which is the largest single item of his diversified operations. Strawberries come next on the list. He says the bees are the most variable in regard to annual production. One hundred and twenty-five colonies are kept. His "farm" has no chickens; and his chicken story, comparing it with bees, is highly interesting and humorously written. Here it is:

When I bought my farm I did not intend to raise chickens. I had been through the chicken-mill. Upstairs somewhere there is a big box that contains my chicken things. There are a good many dozen ribbons—lots of them blue; several diplomas and five silver cups, all won at the state poultry shows of Kansas, Missouri, and Nebraska; also in the box are caponizers, leg-bands, lice-powder, many dollars' worth of chicken medicine, and enough literature to instruct anybody how to get rich in the chicken business.

I had the chickens when I was in business. I raised and showed them for fun—they paid me in fun. The few hundred dollars I got in spring and summer for hatching eggs, and in fall and winter for exhibition and breeding birds, just about paid expenses.

It pays the general farmer to raise chickens. He has grain, and keeps stock. On such a place the fowls have a wide range, and the waste grain goes a long way toward keeping them, but nothing of the kind on a small place. Try it. Buy your feed at market prices. Sell your eggs and meat on the market. Keep books. See how you come out. I doubt if there will be enough left to buy the next new brooder that comes out.

But while I was in the business I had another diversion that stuck, and stuck on its merits—bees. Bees are the most interesting proposition I have ever wrestled with, and for profit they have chickens backed clear off the right of way. They don't need incubators, brooders, chick feed, nor grit. They don't have lice, mites, roup, limber neck, liver trouble, nor cholera. You don't have to get up in the middle of the night to see that a lot of little chicks are not getting chilled, nor chase away some prowling cat or skunk. You don't have to hustle a lot of one-pound birds into their coops before a big rain for fear the lunatics will stand out in the storm and get drowned. Bees know their business, and attend to it. Bees can be kept anywhere in the United States, and almost anywhere they will show a profit if properly managed. A back yard big enough for a coal-box is space enough for two or more colonies of bees. They are kept in garrets and on roofs of buildings in large cities. Almost any spot big enough for the hive will do, and a mighty small place will accommodate a hundred hives.

BEEKEEPING IN CALIFORNIA

P. C. Chadwick, Redlands, Cal.

Mr. Arthur C. Miller gives an interesting account of stopping a bad case of robbing. It is interesting to me because of the fact that no argument can convince me that I would not be getting into a worse muss than ever if I tried the same plan in my apiary.

I am glad to note that the necessity of producing a clean ripe quality of honey is constantly increasing. The present depressed condition of the market is having a wonderful influence in this respect. The beekeeper has come to the realization that, if he is to sell his product, it must be up to a high standard in color and body. A few with whom I talked at our state convention argued that the producer can still sell a thin honey at a price almost equal to the heavier qualities, and very much more could be produced. This idea should be discouraged—first, for the reason that it is not strictly honest; and, second, because it has a depressing influence on the market. When a consumer buys a poor grade of honey that sours on his hands he is very reluctant about buying more. Then, too, I am of the opinion that thin honey will not pass the inspection of consistency required by the pure-food law. It is greatly to be hoped that it will not, for that would eliminate it from the market quicker than any argument. There are many of our producers who are none too particular about this point in honey production. It should be the object of every producer, however, to put up an article that would give him first thought in the minds of honey-buyers.

In this connection I am going to rehash my views on the necessity of plenty of comb room. There are many who argue that there is a great loss in waiting for honey to ripen. This is quite true when there is a lack of room in which the raw nectar can be stored while the ripening process is in progress. That is why I am always preaching plenty of room. Now, by plenty of room I do not wish to convey the idea that an unreasonable amount of combs should be placed on the hive. In fact, I hold the opinion that no more than two supers above the brood-chamber should be used in producing extracted honey. When tiered up to a greater height there is both time and bee force wasted—time, because of the necessity of the bees having to go so far from the entrance to such a great height; bee force,

because, when the product is finished, it will be constantly guarded by bees that might be better employed. The season should be started with a single super. If the season is favorable when sealing is begun, another super of empty combs should be placed under. When sealing begins in the lower the upper will be ready to come off, be extracted, and be replaced under the remaining super. In this way plenty of room can be furnished for the raw nectar while the ripening of the upper super is being completed. That a crowded condition follows the single-super plan, causing a great loss, there is no doubt. I have tested this out on the scales to satisfy my own mind. Take a single super that is a half to two-thirds sealed when nectar is coming in freely; weigh the hive for two or three days, then place an empty super of combs under, and note the increase in the daily weight.

In the editorials, page 94, Feb. 1, will be found some data relative to the chilling of bees in winter, that may well be considered by us in "sunny" California—not that we have temperature that hovers below the zero-mark, but that we lose many bees by being chilled in the field. In the above-mentioned editorial an instance is given where bees were suddenly chilled by a cold wind and rain storm, while at play, and were unable to return to their hives. A coat of ice was frozen over them for a period of three days, after which they were thawed out and warmed sufficiently to enable them to return to the hive, which they did. I have had such a variety of experiences with freezing, chilled, and so-called "winter killed" bees, that at the present time my mind is unsettled on the subject.

Our loss during the spring months by bees being chilled while in the field is a well-recognized fact. If a bee will stand the plight of being frozen in a coat of ice for three days and then be able to return to its hive, why should our loss be so great? There is seldom more than a few days at a time when the sun does not shine sufficiently to give any bee that may have been chilled by the wayside sufficient warmth to renew its activity. Then what becomes of bees that are left in the field on cold days?

During the later 80's I made some observations in the East relative to bees remaining in the field over night. I satisfied myself that they quite often did so, returning in many instances in the early dawn when

no bees had left the hive going to the field, and proved to my satisfaction that they were returning from the previous day's trip. But there the climate is quite different from ours in the West. The night air is quite often as warm as during the day, and the only reason a bee would have for staying out would be that of being overtaken by darkness. I have made similar observations in this state, but have concluded that, if a bee is left in the field over night, it either never returns, or is so late in the day returning that it could not be told from any others that were returning. This is explained principally by the fact that at sundown here the air begins to cool rapidly and they are warned of night's approach, which drives them homeward.

But our loss seems to be from chill that occurs during the day, and holds them out during the day or even longer. There is a loss, and a heavy one; but why, I am not able to say positively at this time. There is a possibility that, when a bee is overcome with cold when full of nectar, it may not have the recuperative power that it has when not loaded. The heat generated by the bee's body may be sufficient to revive it; but when cold nectar fills its sac, and it is unable to disgorge it, it may not have sufficient heat to overcome the chill of the nectar. We find them dead under orange-trees and on the sage and other flowers after they have fallen victims to cool air.

Mr. Doolittle makes some interesting suggestions in the March 1st issue about breeding bees for certain purposes. After opening several phases of the matter he asks if there is a reader who can give any light. He has opened a good field for thought, and as he has asked for light I will give at least some suggestions. There may be a difference worth breeding for in the ability of some strains to reach the honey of certain flowers that others fail to reach. I am not ready to believe that a strain of bees bred in New York or Iowa will work differently than the same strain would in this state. There is a possibility that a strain bred for many years in the South would not winter as well in the North as northern-bred bees. The period of time that would be required to bring about any great change would be more than the allotted time of man.

Such changes come about with an evolutionary rather than a revolutionary movement. With the modern way of transporting queens many hundred and even thousands of miles, and the constantly changing of blood from north and south, it is hardly likely that any great variation will ever be

noticeable—at least until many generations have been bred under the same climatic conditions. It is quite true, as Mr. Doolittle says, "It is one of the laws of nature that the further north or south of the equator any animal or plant can live, the tougher and harder it becomes." But this very law of nature was established after many years of gradual hardening and adaptation. When we compare the life of a bee to that of other forms of animal life it is indeed very short, and I believe a change in climate would not affect more than a generation or two of bees. There may be, however, a greater difference than I am aware of.

I have noticed that the bees from queens shipped to this climate from the North are more subject to paralysis than our native-bred bees; but the same has been true of queens from Texas and other southern localities. I have never noticed that there was any material difference in those raised in the South from those raised in the North. My experience with southern-raised queens shipped to the North was made some years ago, and I am somewhat hazy on the exact results of my experiments. It is not my intention to say that all queens from the North produce paralytic bees in the South, but, rather, that it is more prevalent than with those bred in the South.

On this line the thought comes to me that we have the two phases of the situation very near home. Some may remember an article I had in these columns a year or so ago, on bee life in the San Bernardino Mountains. The bees that now inhabit those higher altitudes, where snow covers the ground from early winter until late spring, are the bees that a short time ago nestled under the orange-trees of the valleys. It is even possible that the swarm of last summer is now wintering near the timberline where the temperature hovers near the zero-mark during the entire winter. I have no doubt that a colony taken direct from our valley apiaries to the zero weather of the higher mountains would winter fully as well as those that have been in the mountains for many years. There has been an effort for many years in this climate to acclimate orange-trees to stand a lower temperature; but the result was much like the man's horse that he had trained to eat less and less until, when the job was finished, the horse was dead. There is, as Mr. Doolittle says, "a difference in different colonies in the same locality as to the successful outcome at the end of the season." But we find the colony that forges to the front this year is, as a rule, behind the average the following year.

CONVERSATIONS WITH DOOLITTLE

At Borodino, New York.

PREVENTION OF AFTER-SWARMING.

"Will you tell us how to control after-swarming? Last year during haying time, after the colonies had all cast their prime swarms, after-swarming became a perfect nuisance."

Persistent after-swarming is one of the disgusting things where natural swarming is allowed, and is hard to stop after the bees once get started. Some of our practical beekeepers depend upon hiving the prime swarm in a new hive on the old stand, and immediately carrying the old colony to a new stand a rod or more away, reasoning that, with the loss of bees which go with the swarm, and by a still further loss by all of the flying bees returning to the old location and joining the swarm, the parent colony will be so reduced that the bees will of themselves give up all idea of further swarming. They tear down all queen-cells but one, or destroy all embryo queens after the first young queen has emerged from her cell. Thus after-swarming will be done away with by this one change of location with the old colony. This does not always work in all localities, for there is an occasional colony which will settle down in an hour or two after being carried to a new stand, so that the flying bees do not "draw" off, as it is expected they will, and thus enough are left, with the hundreds and thousands continually coming from the maturing brood, to cherish the immature queen-cells, so that perhaps one colony out of four will go on with after-swarming.

Other practical beekeepers consider a modification of the above to be almost perfect, claiming that not one colony in fifty will ever send out an after-swarm if the modified plan is used, which is: Reduce the bees in the parent hive by hiving the prime swarm in a new hive on the old stand, then gradually turn the old hive around beside it till the entrance faces at a right angle from that of the new hive. Next set this old hive on the opposite side of the new, with the entrance facing the same way as the new, and as it did when the swarm issued, then gradually turn it toward the left. In four or five days the most of the flying bees will have joined the swarm in the new hive. In two days more, or seven days in all, at about two o'clock, when the bees are flying freely, the old hive is to be carried to a new stand, and left there. This gets the new recruits of flying bees in with the swarm, and still further reduces

the bees in the old hive till there are no more left than to care for the small amount of brood. For this reason all thoughts of swarming are taken away, the immature queens slaughtered in their cells, and the young queen, due to emerge from her cell on the seventh day after the prime swarm issued, becomes the mother of the colony. If, in addition, the super that was on the old hive when it swarmed is immediately taken from the parent hive and put on the new hive into which the swarm was placed, this will not only reduce the bees in the old hive, but give an impetus to the swarm by way of making it at once enter the sections. This impetus, together with the many young bees that are thrown in with the swarm, with each turn of the old hive, will lead to a greater yield of section honey than under any other circumstances. Good results can be secured, especially where light hives like the Heddon are used. But with the ten-frame Langstroth or any double-walled or chaff hives, this gradual turning of the old hive and carrying it to a new stand is a laborious, time-consuming operation.

The plan which suits me best is to hive the swarm on a new stand, allowing the parent colony to remain where it always stood, and in some short way putting the date of issue of the prime swarm on this old hive. On the evening of the eighth day go to this hive and place the ear against the side of it; and if the bees have concluded to cast an after-swarm you will hear the first-emerging young queen piping above the gentle humming of the bees inside. If you do not hear it, listen just a moment each evening till the fifteenth day. If not then, you may know that no swarm will issue from that hive as an after-swarm. If you do hear it, you may know that one of the young queens has emerged from her cell and is at liberty among the bees, and that an after-swarm is likely to issue the next day. The next morning, after hearing a queen piping, open the hive and shake the bees off each frame of comb, when you will carefully look for queen-cells, pinching off every one as soon as seen, and shaking the bees in front of the entrance, into which they will run as fast as shaken. If the colony does not have a super, put one on, when all swarming will be done away with, as you are certain that the bees will now have only the one queen which was piping. When worked in this way, both the new swarm and the old colony will give good results in section honey.

GENERAL CORRESPONDENCE

MOSES QUINBY, FATHER OF PRACTICAL AMERICAN BEEKEEPING

BY LYMAN C. ROOT

On account of my long acquaintance with and relationship to Mr. Quinby, I welcome with the greatest satisfaction this Quinby number of *GLEANINGS* and the reprint of the first edition of his "Mysteries of Beekeeping." This spring is the fortieth anniversary of his death; and the facts of his life, familiar to all beekeepers at that time, will bear repetition now for the younger generation.

Moses Quinby was of English stock, descendant of William Quinby, who came to America prior to 1664, and settled in Westchester County, being one of its patentees.

FIG. 1.—Moses Quinby's home in Greene Co., N. Y.

The family continued to reside in this county, and Moses Quinby was born in the town of North Castle, son of William Quinby and Hannah Sands, on April 16, 1810. During his boyhood his family removed to Coxsackie, Greene County, New York; and living in both places in the country he was early associated with life on the farm and in the woods and fields, and his knowledge of the habits of birds and animals began at an early age.

Here in the town of Coxsackie, in 1828, at the age of 18, he earned his first money, working in a sawmill, and with it purchased his first swarm of bees and began the twenty-five years of study and experiment which prepared him for the writing of his book, published in 1853. In 1832 he married Miss

Martha Powell Norbury, also of English extraction, and, like Mr. Quinby, a Quaker. They were married at the Norbury homestead. From this time till his removal to the Mohawk Valley he lived at the home shown in Fig. 1. There was a mill on the place, the ruins of which may still be seen in the picture on the cover of this number of *GLEANINGS*, and he earned the support of his family in these early years running the turning-lathe and doing cabinet work, many specimens of household furniture made by him being now the valued possessions of his granddaughters. Here also he

made his hives and the first honey-boxes. It was gratifying to me on a recent visit to find remaining, after eighty years, so many evidences of Mr. Quinby's work at his early home. In Fig. 2 may be seen the terraced side hill where his rows of hives were arranged. I have reason to believe that at this period there were more bees kept in this section than in any other part of the United States. For years after Mr. Quinby's death I have been to this location to buy bees to replenish my

home apiaries. On a recent visit I saw small apiaries, many of them using the form of hive Mr. Quinby had recommended.

He says he "commenced without any knowledge of the business to assist him, save a few directions about hiving, smoking them with sulphur, etc." Beekeeping was considered a matter of luck. His friends and neighbors on all sides discouraged him. One wise old man predicted failure for him because he potted with them too much, boring holes in the top of the hives and disturbing them. All of this advice only stimulated him to greater action. He prefixed to the word "luck" a big *P*, and underlined it.

Here he spent twenty-five years experimenting and writing, with a determination

FIG. 2.—The terraced ground where the rows of hives stood 80 years ago.

to place beekeeping on the same successful financial basis with other branches of agriculture. All his experiments during this period were made with bees in box hives, there being no better ones at that time.

His first move to avoid destruction of the bees in securing the honey was by boring holes in the top of the hives, and finding that the bees would fill large boxes put over the hive. These were the forerunner of the super and section. Another menace to success in beekeeping was foul brood. Re-reading the chapter in his first book, in the light of the modern science of contagious diseases and bacteriology, shows it to be a marvel of careful observation and accurate

reasoning that would do credit to the present day. The principles of his treatment of the scourge can never be changed. These and many other facts Mr. Quinby found had never been published; so, being by nature philanthropic, and having an unselfish desire to help others in a practical way by sharing his knowledge, he wrote this accumulated experience of twenty-five years into his "Mysteries of Beekeeping Explained, being a complete analysis of the whole subject," as the title-page quaintly states. The book was written in the room pictured in Fig. 3, by the light of a tallow candle. As I reread the book I realize how fully up to date it was for 1853, and how fundamen-

tally correct were his statements and deductions on many points. It bears evidence of being entirely the author's own work. He started with no knowledge of the subject, but with an inquiring and open mind; had no help from others, and only theoretical information from the limited literature on the subject of bees. The key-notes of its success appear to me to be the scientific attitude of its author, unusual at that period—the clearness and plainness of its

FIG. 3.—The room where Mr. Quinby wrote the 1853 edition of his book.

FIG. 4.—The Quinby home at St. Johnsville, N. Y. Mr. Quinby moved here in 1853, the year his first book was published.

style, and the effort to help and instruct the reader rather than impress him with the accomplishments of the writer.

We do not know just when he was able to make beekeeping his sole business and the support of his family; but he certainly did so after his removal to St. Johnsville, Montgomery County, New York, in 1853, the year his first book was published. During the next ten years he owned the largest number of swarms at any time during his business career, and began to send large amounts of honey to the New York market, even while still using the box hive. There being only a moderate demand at that time he nearly glutted the market. This was, indeed, the beginning of the reconstruction period in beekeeping. In 1856 Mr. Quinby's attention was called to Mr. Langstroth's invention of a movable-comb hive. He saw its advantages, and at once adopted it in a modified form. Then followed the introduction of Italian bees, honey-extractor, comb foundation, single sections for comb honey, and his own invention of the bee-smoker. These were indeed gratifying days to Mr. Quinby. Who was there in all of the beekeeping world so well prepared as he from the standpoint of practical experience to meet the needs of this wonderful forward movement?

Mr. Quinby's non-swarming standing frame hive enabled him to accomplish large results under his management. Much might be said in regard to Mr. Quinby's preferring the larger frame. Marked success can be secured only by extremely populous swarms. I have proven the larger frames very advantageous to that end.

I shall never forget the enthusiasm which was caused at our home when the words "centrifugal force for removing honey from the combs" were received in the report of the invention of Major de Hruschka, of Vienna. An old fanning-mill, which had

been used for cleaning grain, was at once taken apart, the fans removed, and wire cloth stretched around its four sides. A larger box was made, inside of which this frame was arranged to revolve, and with the gearing of the fanning-mill it was set in motion. The gratification with which Mr. Quinby saw the honey thrown from the first combs cannot well be described. He soon made an extractor in more workable form, which was afterward perfected by A. I. Root, and known as the Novice extractor.

Mr. Quinby realized that, though fearless himself, people were deterred from keeping

FIG. 5.—Queen, drone, and workers. This exceedingly accurate drawing was made 50 years ago by Mr. Quinby's daughter, who afterward became the wife of L. C. Root. The illustration was used in the 1865 edition of the book, and has been very widely copied. See article by P. H. Elwood, page 281.

bees by fear of being stung. Smoke had been used in various crude ways; but he knew that, if it could be easily and conveniently adapted, it would be a great boon, especially to the amateur. His invention of the bee-smoker did this, being so arranged with upright bellows and fire-tube as to burn standing upright, but to go out when placed on the side, and to be easily manipulated with one hand. The principle of it has never been improved upon.

New York state where Mr. Quinby's in-

fluence was most in evidence, became the largest honey-producing center in the world. One of the first articles he ever wrote on bees for publication was for a Philadelphia paper, expressing doubts as to the possibility of a writer having secured a gain of twenty pounds of honey from a swarm in two weeks. In these later days he had seen that amount gathered in two days, and five hundred pounds of extracted honey taken from one colony in a season. Mr. Quinby sent in these days from five thousand to thirty thousand pounds of honey to the New York market annually.

While essentially a scientist and teacher, his first object was to enable others as well as himself to make beekeeping a commercial success by knowing how to gather in quantity this useful, natural food-stuff and delicacy. As Mr. Quinby became well known from his books and articles in agricultural papers, his home was quite a center for those seeking the information he so gladly imparted. Mr. Quinby was never so happy as when passing on his knowledge and experience to others. Few people who were not personally acquainted with him can realize how devoted he was to his questioners, whether in person or by mail or through the press. From the start to the last evening of his earth life he never proved a principle in bee culture the benefit of which he did not give to the public. Two hours before he passed away he was at his desk, where he left an unfinished article.

Pruning and grafting tools used by Quinby.

The late Captain J. E. Hetherington was one of his most energetic pupils. It is still a joy to me to recall his enthusiasm during his frequent visits to Mr. Quinby's home, and the eager way in which he asked questions and received answers. He soon became one of the large bee-owners, first of box hives, but, as improvements followed, always up to date. Of these early visitors, almost the only one living is P. H. Elwood, of Starkville, New York, then as now the intelligent, thoughtful worker and genial friend.

In 1865 Mr. Quinby published a revised edition of his book, and from the tone of the preface it is gratifying to see his pleasure in the success and popularity of this first edition.

In March, 1870, the Northeastern Beekeepers' Association was organized at Al-

bany, with Mr. Quinby as its first president, an office he held for five years, declining re-election at the meeting preceding his death. He was elected president of the North American Beekeepers' Association, at Cleveland, in 1871, and served one year.

Thus with modest honors and much satisfaction in his work and in the fruit-growing on his place, a happy home life and wide outside interests in the anti-slavery cause, temperance work, and all good and progressive endeavors, the years went by. Death came suddenly on the night of May 27, 1875, and a life of usefulness was over. To quote from obituaries printed soon after: Mr. J. H. Nellis, of Canajoharie, New York, said in the *American Bee Journal*, June, 1875:

Long may we remember the unassuming, pleasant, hearty manner of the man whom we respected as a father! Indeed, his cheerful service of time, money, and hospitality to those who wrote to him or visited him from curiosity or to learn all they could from him, without returning even a word of thanks, was, to others more selfish, a matter of much surprise.

Our feeble words fail to express the deep appreciation which we had of Mr. Quinby. We consider him the most successful founder of modern bee culture in America, and a man of unswerving conscientiousness, truth, and purity.

In short, we sum him up as a deep, progressive thinker, a real philosopher, and a genuine philanthropist, who should long be held in grateful remembrance by the American people.

Captain J. E. Hetherington, in his presidential address before the Northeastern Beekeepers' convention, at the meeting following Mr. Quinby's death, summed up his character as follows:

His life has been in every sense a life of usefulness, and not wholly devoted to the interests of bee culture, for he took a living interest in any movement he thought would benefit society; and as an advocate and helper in the temperance work he did no mean service.

He possessed true kindness of heart, and regarded it a religious duty to make all better and happier with whom he came in contact, and regarded that life a failure that did not leave the world the better for having lived.

I am writing this article with the extreme desire to show Mr. Quinby's devotion to his chosen calling. It would be impossible for any one who did not come in daily contact with him in his manipulations of bees, in the beekeepers' conventions, and, most of all, in his home, to have a full appreciation of how completely his work filled his thoughts. How well I remember the emphasis he gave the words when he once said to me, "I want it distinctly understood that I cannot afford to spend my time making money!"

He gave forty-seven years of constant application in honest effort to place beekeeping on a firm business basis. I am

somewhat acquainted with the history of the beekeeping of the past, and I feel justified in pointing with pride to these forty-

seven years of devotion which should warrant the name of "Father of practical commercial beekeeping in America."

UNCLE QUINBY IN THE OLD DAYS

BY HIS NEPHEW, T. S. UNDERHILL

In calling up early boyhood remembrance of Uncle Quinby I make note of a few distinctive features of intimate social or family characteristics which were of a cordial, happy nature, such as playing the flute, his military outfit as captain of militia, and particularly his quaint sayings and axioms for which he was noted, such as: "Subdue your appetites and you conquer human nature;" "What you get for nothing is apt to be mighty expensive;" "When a man boasts of acting disinterestedly, it's safe to say he has an ax to grind;" "The lucky man is one who locks the door before the horse is stolen." One time, when, boy-like, I was proudly sporting a finger-ring, he said, "Tommy, I have always noticed that pigs that have to root for a living don't want to be rung."

His helpfulness and wise counsel were widely recognized. To us boys he was undoubted authority and an impartial judge. I well remember the early rural home in the town of Coxsackie, New York, where the Quinby residence was on a hill that we called "Honey Hill," in contradistinction from the valley called "Honey Hollow," of which the creek fed the mill-dam pond at the foot of the hill. This early remembrance dates from about 1840, when I was five years old—at least before my school age, as I would go with an older brother on his way to school and spend the day at Uncle Quinby's. This boyhood association with Uncle Quinby was maintained all through youth and early manhood. I remember the milldam, the water-wheel, and the turning-lathe in his cabinet-shop were the wonder and delight of my boyhood days. A day at Uncle Quinby's was a rare treat. "Honey Hill" was a veritable garden of Eden, paths bordered with flowers and fruits in abundance, and the bread and honey was, perhaps, best of all.

The most prominent recollection of the early beekeeping days, before and up to the time of publishing the first edition of "Mysteries of Beekeeping Explained," was the great attraction of his observatory hives, common box hives with glass sides and wood shutters. There is where his first study of the habits of the bee commenced.

I remember it was my delight to watch these inspections, his showing me the bees at work, and pointing out the different kinds of bees, especially the queen, and explaining the head of the colony was a queen and not a king as it was usually called in those days. He showed the different cells, particularly the queen-cell, with its wonderful history of construction, and told that at its completion and maturity the young queen would make a piping sound, which would foretell a coming swarm, and then we would, at evening time, listen for the signal at a hive that showed indications of swarming. Sure enough, next day the swarm would come forth, the mother queen with them. This we knew from the fact that I had seen Uncle Quinby catch her in a tumbler as she came out; and wherever he placed her the swarm would alight. These observations and experiments are still fresh in my memory, and in a measure will show the difficulties that attended this early research in those primitive days of beekeeping. From these primitive methods was evolved not only the nature and habits of the honeybee, but the successful practical management of bee culture for producing honey in quantity in marketable form.

This led to the larger field of operation in the Mohawk Valley from 1853 to 1859, during which time I was associated with Uncle Quinby in the management of a number of apiaries in Montgomery and adjoining counties.

In these old box-hive days, the fire and brimstone period of beekeeping, the development of the honey-box was as follows: First: surplus honey in wooden boxes from the top of the hive; next, two 6 x 12 boxes with glass on four sides, under one cover; then four boxes, 6 x 6; after which six boxes, 4 x 6, under the same wooden cover. This was the method employed in securing surplus honey up to 1859, when my connection with the business ceased.

This was the evolution I saw develop under the guidance and direction of Uncle Quinby, whose standard of life was of the highest order, and whose bequest of practical beekeeping was excelled only by his exemplary character, honesty, and integrity.

MOSES QUINBY—A TRIBUTE TO HIS MEMORY

BY P. H. ELWOOD*

Read before the Northeastern Beekeepers' Association, February 3, 1876.

In the history of every profession or occupation we find the names of a few who have outstripped all competitors—men possessed of that rare gift, power of original thought; pioneers who have explored an unknown wilderness, and mapped it for future possessors. In the history of bee culture there are four names that stand out prominently beyond all others: Huber, Dzierzon, Langstroth, and Quinby. Huber, the blind apiarian, who, by his great ability and untiring perseverance, discovered more of the interior workings of the beehive than any other man who ever lived; Dzierzon, the Quinby of Germany, who confirmed the wonderful discoveries of Huber, and added that equally wonderful one of parthenogenesis; Langstroth, our own countryman, inventor of the movable-comb hive (without which there would be no occasion for gatherings like this), and author of a work on beekeeping that, for scientific accuracy and beauty of expression, is not only unsurpassed but almost unsurpassable; and last, but not least, our own Quinby, inventor of the

beekeeping to the dignity of a pursuit among men, and he performed his work well. Beekeeping as a speciality will date from his time; and if Huber has earned the title of "Prince of Apiarians," certainly Mr. Quinby is entitled to that of Father of

Moses Quinby

bellows smoker, who, adding largely to the knowledge of his predecessors, combined the whole into a system of practical management unequalled in simplicity and feasibility.

Mr. Quinby's lifework was to elevate

P. H. Elwood, Fort Plains, N. Y. One of the numerous successful students of Quinby.

Practical Bee Culture. He sowed that we may reap. He labored without reward—often, indeed, without an appreciative public. Now that he is gone, beekeepers will miss his counsels, and think more highly of his work.

While he was anxious that the millions of pounds of honey now lost might be gathered, he had no fear of an overstocked market, and often narrated the history of the cheese trade as an illustration, saying that, while this industry was in its infancy, prices were lower than at present, and that the market was really in more danger of being overstocked than now, as the facilities for disposing of the product of the dairy have increased faster than the production. The

* See prenote to Mr. Elwood's further article, page 281.

history of this business he thought would be the history of ours. There may be temporary gluts in this market, as there are in all others; but these will be, not because more is produced than can be consumed, but because the facilities for handling the crop are undeveloped. Our greatest enemy today (outside of those who sell glucose for honey and paraffin for beeswax) is the old-fogy beekeeper who brings his honey to market in the most unattractive and undesirable packages. A small quantity of his honey will supply a large town, and the

prices he establishes often prevent the introduction of better goods. It is to our pecuniary interest to make better beekeepers of such men. Yet while Mr. Quinby was doing just this work, very many beekeepers thought him to be seriously injuring their business, and were for ever crying out, "My occupation is gone!"

High as Mr. Quinby ranked as an apiarian, he stood still higher as a man. We who were accustomed to gather at his fireside can never forget his wholesome hospitality. He was a true gentleman, unfettered by the

Moses Quinby and family. This picture of Mr. Quinby is probably one of the last taken, if not *the* last. See the farther article by Mr. Elwood, page 281.

stifling conventionalities of modern life. He was always the same, always having a hearty welcome for his friends and a pleasant word for every one. True to his Quaker education, he was an intense hater of shams, especially of the human kind.

He was honest—a characteristic that is getting to be as scarce as it is valuable. There is no principle in business better established than that "honesty is the best policy." Mr. Quinby, unlike most men, was honest from principle.

The mental rather than the motive temperament predominated in him; that is, surplus vitality would more naturally develop into extra mental work than into intense muscular activity. He was a thinker, an investigator; an originator rather than an imitator. He was calm and deliberate, not excitable; did not plan one minute to execute the next and destroy the following. As he viewed a subject from many standpoints he was not quick in forming conclusions. In quickness he could not keep pace with many who were of lighter caliber than himself. Muskets sometimes hang fire, but big cannon are not usually handled with the rapidity of small arms.

While not easily disturbed in temper, he was not tame in spirit when he had just cause for indignation. He had a very modest opinion of himself, and in measuring others did not set himself up as the standard of perfection.

His last years were his best. His best and most enduring work was done after he was sixty years old. His famous assertion

then made, and so ably defended, that cold usually kills the bees, has never been successfully contradicted. He never wrote so well as in the latter years of his life. He continued to improve in both subject matter and manner of expression. His bodily powers were gradually failing him, but his reasoning faculties were never so keen as in the last five years of his life.

With more of the elements of the politician about him he would have ranked higher in life, but his reputation would not have been so enduring. Now his merits are just beginning to be appreciated.

How fitting that a life so calm and pure should have so peaceful an ending! On the 27th of May last he retired at his usual hour in seeming good health and spirits. Before the hour of midnight, without awaking from his slumbers, he quietly passed from time into eternity. Thus, at the age of sixty-five, ended the life work of our counselor, friend, and public benefactor. He was more fortunate than the most of men, for he was able to take with him his most valued possession, the hard-earned accumulation of a lifetime—a noble character.

So live that, when thy summons comes to join
The innumerable caravan that moves
To the pale realms of shade, where each shall take
His chamber in the silent halls of death,
Thou go not, like the quarry-slave at night,
Scourged to his dungeon, but, sustained and soothed
By an unfaltering trust, approach thy grave
Like one who wraps the drapery of his couch
About him and lies down to pleasant dreams.

Starkville, N. Y.

MOSES QUINBY, THE FOUNDER OF COMMERCIAL BEEKEEPING IN AMERICA

BY ARTHUR C. MILLER

Moses Quinby was a pioneer beekeeper. In 1828 he plunged into the wilderness of bee-life with no other knowledge than how to sulphur bees and a few directions about hiving swarms. Without veil or smoker, with black bees in box hives, he worked and won. Not until he had kept bees some years did he see any text-books, and these were imported ones containing little or nothing of value but what he had already found out. Their errors and mistakes were to him an incentive to further research and closer observation. In the preface to his book he says:

It is folly to expect success in beekeeping for any length of time without a correct knowledge of their nature and instincts; and this we shall never obtain by the course hitherto pursued. As much of their labor is performed in the dark, and difficult to be

observed, it has given rise to conjecture and false reasoning, leading to false conclusions.

When I say a thing is so or say it is not so, what evidence has the reader that it is proved or demonstrated? My mere assertions are not expected to be taken in preference to another's. Of such proof we have more than enough. Most people have not the time, patience, nor ability to sit down quietly with close observation and investigate the subject thoroughly. Hence it has been found easier to receive error for truth than to make the exertion necessary to confute it—the more so because there is no guide to direct the investigation. I shall, therefore, pursue a different course; and for every assertion endeavor to give a test that the reader may apply and satisfy himself, and trust to no one. As for theories, I shall try to keep them separate from facts, and offer such evidence as I have, either for or against them.

And he did. Every thing must be tested and proved, no guesswork was allowed, and his genius in devising ways to discover the

secrets and actions of bees was wonderful. Nothing was too minute to receive his consideration. His analysis of observed conditions and reasoning back from them to the causes has not been surpassed.

But every thing was done with one end in view—efficiency in his work. Simplicity of apparatus was his constant effort, and in his writings we find frequent reference to costs and profits.

He was making money from his bees while most of the rest of the beekeeping world was trying to learn how to retain any bees at all. The wax-moth was the bane of their existence, while to him it was merely an incentive to keep all stocks strong and to do better beekeeping. The moth was to him an annoyance rather than a menace.

It was not until he had been keeping bees for many years that he had any other smoking-device than the pan of burning tinder on the roll of smoking rags, and then he devised the tube "pipe," later described and illustrated by Alley. This device was a tin tube five to six inches long and half an inch or more in diameter, with a conical wooden plug in one end and a pipestem-shaped plug in the other, both with a hole lengthwise through them. This was filled with tobacco, and held in the teeth when at work, the breath being blown out through it instead of drawn in.

It was years later when he invented the bellows smoker which is now such a necessity to all of us.

A bee-veil he knew nothing of until about 1858, previously using a handkerchief over the back of his head and neck when bees were particularly troublesome. At that time he learned of the wire-cloth protection described by Langstroth, and from it evolved the style now sold under the name of "Alexander," but later Mr. Quinby improved it greatly.

American foul brood he encountered about 1833. He traced its spread to infected honey, and originated the "driving" plan of treatment, of late years called the "McEvoy" or "shake-off" plan, but really Quinby's. Also he speaks of Italians resisting the disease better than blacks.

Quinby was observing, analytical, and resourceful, somewhat impatient with the baseless whims and practices of others; but this attitude was tempered by a kind heart, and with a quiet sense of humor which constantly crops out in his writings.

Here are a few of the very many good things he has said, picked at random here and there, to illustrate his views, the difficulties he labored under, and the way he surmounted them.

He suggested the use of tobacco smoke in the cellar to quiet uneasy bees when taking them out.

As a pollen substitute, he used rye and buckwheat meal or flour mixed with sawdust, and fed on a floor a few feet square with a rim around it, and put on only a few quarts of flour. Those of us experienced in using pollen substitutes will at once see the reasons for and the soundness of his instructions.

Of buying bees he said, "The heaviest hives are not often the best." In writing of preparing bees for winter he says:

There is almost as much diversity of opinion with respect to wintering bees as in the construction of hives, and about as difficult to reconcile.

Excessively large colonies are unprofitable, as well as too small. Avoid extremes.

Also:

A first-rate stock may be wintered with very little care in almost any situation; but those of second and third rate require some special attention.

That is a fact worth remembering when we are considering winter cases, etc.

His methods of freeing supers of bees were almost identical with those used by Dr. Miller. They must be good when two such men use them in commercial work. In the days of box hives he writes:

But what kind of hive shall be made? In answer some less than a thousand forms have been given. The advantages of beekeeping depend as much upon the construction of hives as any one thing; yet there is no subject pertaining to them on which there is such a variety of opinions, and I have but little hopes of reconciling all these conflicting views, opinions, prejudices, and interests.

Of the cost and value of combs he says:

One important item should be considered in this matter by those who are so eager for new combs. It is doubtful whether one in 500 ever thought of the expense of renewing comb. I find it estimated by one writer that twenty-five pounds of honey was consumed in elaborating about half a pound of wax. This, without doubt, is an overestimate, but no one will deny that some is used. I am satisfied of this much, from actual experience, that every time the bees have to renew their brood-combs in a hive they would make from ten to twenty-five pounds in boxes; hence I infer that their time can be more profitably employed than in constructing brood-combs every year.

Non-swarming hives he placed no reliance in, for he says:

Further, these non-swarmers are not always to be depended upon as such. They will sometimes throw off swarms when there is abundant room in the hive as well as in the boxes.

But if such hive is only half full, or 2000 inches, it is very common for them to swarm without adding any new comb—proving very conclusively that a hive that size is sufficient for all their wants in the breeding season. When about 1200 inches only had been filled the first year, I have known them to add combs until they had filled about 1800, and then cast a swarm, proving also that a little less than 2000 will do for breeding.

Eighteen hundred cubic inches is close to the comb content of ten L. combs.

Listen to this on bees moving eggs and signs of queenlessness:

During the spring months, in medium and small families, where the bees can protect with animal heat but a few combs, I have often found cells containing a plurality of eggs—two, three, and occasionally four, in a single cell. These supernumeraries must be removed, and frequently may be found amongst the dust on the bottom-board.

If you have a hive that you suspect has lost a queen at this season, her presence can be ascertained nine times in ten by this method. Sweep off the board clean, and look the next day or two after for these eggs. Take care that ants and mice have no chance to get them. They might deceive you, being as fond of eggs for breakfast as any one. When one or more are found, or any immature bees, it is sufficient; no further proof of the presence of a queen is needed.

The public of his day had many of the same prejudices and animosities as that of to-day. Among the notions was the belief in loss to crops through the nectar taken by the bees. He met it by the same answers that we do.

Of the sagacity of bees he writes:

On this subject I have but little to say, as I have failed to discover any thing uncommonly remarkable, separate, and distinct in one swarm that another would not exhibit. I have found one swarm, guided alone by instinct, doing just what another would under the same circumstances.

Then he proceeds to cite many of their wonderful acts, which, by the way, they do in exactly the same way to-day, and concludes by saying:

I have mentioned these to show that a course of action called forth by the peculiar situation of one family would be copied by another in a similar emergency, without being aware of its ever being done before. Were I engaged in a work of fiction, I might let fancy reign and endeavor to amuse, but this is not the object. Let us endeavor then to be content with truth, and not murmur with its reality. When we take a survey of the astonishing regularity with which they construct their combs without a teacher, and remember that the waxen material is formed in the rings of their body—that for the first time in life, without an experienced leader's direc-

tion, they apply a claw to detach it, that they go forth to the fields and gather stores unbidden by a tyrant's mandate, and throughout the whole cycle of their operations one law and power governs. Whoever would seek mind as the directing power must look beyond the sensorium of the bee for the source of all we behold in them.

Here is his statement concerning Langstroth's book and hive, written after he had used the hive for a couple of years:

Unexpectedly, I think I have found a hive superior, in many respects, to the simple box. It is not pretended that a swarm of bees located in it will store a greater amount of honey in a given time; but the advantages are in the control of their operations, and knowing their condition at all times.

From this he soon went entirely into the use of frame hives, modifying them in size and shape to meet his own ideas, saying:

It is not very likely we have got the best form of the hive. I have one quite different from Mr. Langstroth's, the patentee; but whether it is better is for others to decide. I can only say that I am suited with it better than with his. A few will like mine because I do; others, his because he recommends it. I have not the least objection to any one's improving it or using it as either of us does. There is not the least doubt in my mind that whoever realizes the greatest possible benefits from his bees will have to retain the movable combs in some form. The principle (movable combs) can hardly be dispensed with.

The more we read Quinby's writings, the more we admire and like him. Had his work been given the same publicity as Langstroth's, it is difficult to doubt that commercial beekeeping would now be far ahead of what it is. Quinby was a great pioneer, and to-day his book is as good and as valuable as ever. It is one of the classics of bee culture, and no beekeeper can rightly feel well posted in the art until it has been read.

To Quinby the beekeepers owe a great debt, and of him we can truly say the world is better for his having lived.

Providence, R. I.

A DAY WITH M. QUINBY

BY J. E. CRANE

It was in the autumn of 1869 that I spent a day with M. Quinby. A year or two before I had bought several hives of Italian bees of him, including a real imported queen, paying \$20 for her. More than this, I had read and reread "Mysteries of Beekeeping Explained." In fact, I had studied it until I almost knew it by heart. The old book, as I look at it now, appears to be pretty well worn out. I believe most earnestly the words found in the preface of this book, "The simplest directions of a reliable practical beekeeper who studies the science with an honest enthusiasm are invaluable to the tyro in apianian knowledge." I be-

lieved the principles laid down in his book were the sure foundations of success if faithfully followed. More, I believed Mr. Quinby the largest or most experienced and successful beekeeper in the United States.

The season had been a good one with me, with a good crop of honey secured by following the directions given in "Beekeeping Explained." How better could I spend some of the money the bees had brought me than by visiting this prince of beekeepers?

It was late September or early October when I went to Troy, stopping over night and completing the journey the next morning, that I might have a full day with him

at St. Johnsville. The name of that town still has a charm for me, different from any other on the face of the whole earth.

Leaving the train at the station I soon found the unpretentious home of Moses Quinby, and introduced myself to him as well as my embarrassment would permit. I found him, with the assistance of L. C. Root, engaged in the somewhat prosaic work of feeding bees. His method of feeding was quite different from any thing I had ever heard of, and I will give it.

One or more combs were laid down flat in a tank, and sugar syrup or honey poured upon them from above in such a way as to fill the cells. Then the combs were turned over and the other side filled. After the surface honey had drained off they were given to the bees in exchange for empty ones, and the job completed at once. I have used this method several times in early spring when I had no combs of honey to give to colonies short of stores. This season had been a very poor one in that part of New York. Mr. L. C. Root told me at that time that not a single wild colony would survive the following winter, and, as a consequence, there would be no difficulty in rearing purely mated Italian queens.

I was invited to take dinner with his family, and was duly introduced to Mrs. Quinby and a daughter. There was one thing that puzzled me; and that was to determine the relationship of L. C. Root to the family. Was he just a helper, or was he a son-in-law to Mr. Quinby? I had never heard of him before. I thought it would not be quite the thing to inquire, and so the puzzle remained; but of one thing I felt sure—that if he was not a son-in-law he was likely to become one at an early date.

To the east of the Quinby home the ground rose quite steep from the Mohawk Valley, and the ground had been terraced and set to grapes, which were then ripening.* After dinner Mr. Quinby went out with a large basket on his arm to gather grapes for an hour or two. This gave me an opportunity to visit with him without interruption, and I appreciated it most fully. I told him of the extractor I had made, and with which I had secured 240

lbs. of honey during the preceding summer from one colony. He told me of making one himself, using the gearing of an old fanning-mill for his extractor, and showed me a part of it; but the season had been so poor he had not used it.

He told me of a young friend of his who, he thought, had met with unusual success, and urged me to visit him. I thought I could not at that time, but did later, and found him to be none other than Capt. J. E. Hetherington. He told me also of his brother, D. W. Quinby, of New York, who was a commission merchant, and to whom it was safe to consign honey for sale, and to whom later I shipped many tons of honey.

The latter part of the afternoon, he with Mr. L. C. Root went over a lot of small nucleus hives, looking for young laying queens. I noticed that he used no smoke, and seemed to get along very well—rather better than Mr. Root did.

The impression Mr. Quinby left on my mind was that of a kindly, elderly man, not as talkative as some beekeepers I have known, but all he said was to the point, and had weight. He seemed glad to help a beginner in beekeeping—glad to let his light shine rather than to cover up what he had learned lest others should profit by it, although he made no display of his superior knowledge and experience.

That Mr. Quinby laid the foundations broad and deep for practical beekeeping on an extensive scale there can be no doubt. He cleared away the fogs and mists of ignorance that hung over the mysteries of the hive, by his own investigations and experience.

The younger generation of beekeepers have no conception of the ignorance of the average beekeeper sixty years ago. Fulton's Clermont, that steamed proudly up the Hudson over a hundred years ago, at the rate of five miles an hour, would not, doubtless, serve as a perfect model for a modern liner; but the success of this experiment laid the foundation of navigation by steam. The progress of beekeeping has gone forward from similar humble beginnings.

Middlebury, Vt.

LANGSTROTH AND QUINBY COLABORERS IN PIONEER BEEKEEPING

BY W. P. ROOT

I trust I shall not be making the personal equation too prominent when I say that very few persons, even among practical

beekeepers, have more keenly enjoyed for thirty years an opportunity to witness the development of an idea or system which once engrossed the attention of the man

* See Fig. 2, page 268.

whose memory is recalled in this issue. I have read all of his writings carefully, especially his "Mysteries of Beekeeping," and rejoiced to note how

He scattered the hosts
Of holgollins and ghosts

till the word "mysteries" became almost a joke. But while I speak of him I do not forget Langstroth, for to do so is to read Romeo without Juliet.

I have no patience with comparisons of some men with others as to their work done for humanity. It reminds me of what our old friend E. E. Hasty once wrote me. He said he had studied for years to find out which one of his shear-blades does the cutting. They work together by working against each other. The physical features of men may be compared, but there comparison ceases.

To carry out some great work, it is clear that Providence has designed at least two persons to do it. This was the case with Quinby and Langstroth, and yet each worked long at the same task without being aware of their partnership. These two men were born the same year, and their early years permitted none of the luxuries and few of the conveniences of modern life.

It commands our admiration when we see a man like Mr. Quinby rising up from the degrading superstitions of his time, brushing away so much of the fog that surrounded him, and getting down to a rational explanation of things by assuming that regularity prevails in God's works.

Mr. Langstroth's invention was beginning to be felt in the world when Mr. Quinby also was startling the commercial world by doing with bees what he himself thought he had shown in print could not be done—yes, doing it seven times over. But his remarkable success (seldom surpassed to-day) arose from his knowledge of the habits of the bee and a close study of the conditions that induce bee diseases and the causes that will check them. His fame had reached Ohio,

and it is not to be wondered at that Langstroth felt that "he must increase, but I must decrease." Filled with annoying surmises, unworthy suspicions, and harassing fears, Mr. Langstroth happened to be here at A. J. Root's home when this evil spirit haunted him the worst. Mr. Root has described how Mr. L. told him one morning his watch had said all night, "Quinby, Quinby, Quinby," adding that he was about to start for Mr. Quinby's home and have a settlement. It was a question whether the prevailing spirit would lead them to shake hands together or shake fists at each other. But the result was a perfect understanding, cementing a close friendship during the short period of life that remained to Mr. Quinby, Mr. Langstroth living twenty years longer.

The fact was, Langstroth had been engaged in perfecting a home for the bees while Quinby had been studying their individual habits, although in this latter respect Langstroth was the peer of anybody at that time. The distinctive lifework of each dovetailed together so nicely with that of the other that modern apiculture has grown up around their inventions as the honeysuckle does around a pole.

Quinby was not slow to adopt movable frames, as he immediately saw their advantage; and if he could have seen by revelation the implements now in use for extracting, etc., he would have said, "The half has not been told."

Although Mr. Quinby said he considered life to be too short to be spent in making money, it is said he amassed at least a comfortable competence, while Mr. Langstroth's inventions and discoveries never yielded him enough for even a support.

But aside from the inestimable benefits conferred on humanity by the labors of these men among bees, we owe them still greater honor for the beauty of the lives they led in their individual capacity; for in all they did they "looked through nature up to nature's God."

A BEEKEEPER'S FEELINGS TOWARD MOSES QUINBY

BY LEWIS L. WINSHIP

No man has done more for the beekeeping fraternity at large than Moses Quinby. He began keeping bees when only nineteen, and, until his death at the age of sixty-five, was actively engaged in trying to help beekeepers. He had only one equal in the United States, and that was Langstroth, to whom was given the honor of inventing the movable-comb hive. What difficulties must

those early beekeepers have passed through! When Quinby first began beekeeping, the old box hive was still in vogue; and when one wished to take off honey the bees must of necessity be smoked with brimstone, as at that early date such a thing as a movable-comb hive had not been thought of. What would the present-day beekeepers do without comb foundation, smokers, and a

La Manda Park, Cal., field meeting at the apiary of F. M. Stone.

hundred and one other very useful articles which make up a beekeeper's world?

These articles are to the beekeeper of the present day what tools are to a carpenter. But in Quinby's day no articles to further the work of the bee were to be had. This made it all the harder for him, a lad of nineteen, to make a success of his chosen profession.

Quinby (unlike many inventors) was not a rich man. He was trying to improve conditions and methods then in vogue in regard to the management of bees. When he invented some article which he thought of value to beekeepers, he gave it directly to them, and did not rush off at once to patent it. Some may call this poor management on his part, and doubtless he would have been a richer man had he patented some of his inventions. But, nevertheless, if Quinby had been as

narrow-minded as some people of his time we should be without many things to-day which have helped further the beekeeper's cause.

I have a copy of "Quinby's Beekeeping" which was published in 1866, and find many articles in it which are worth reading in 1915. This book was published nearly half a century ago, and since that time beekeeping has been nearly revolutionized. Even so, when I have the time, I read the book through, and hardly a year passes but that

F. M. Stone's apiary. La Manda Park, Cal. Geese keep the grass down.

I read it through from one to three times. The book seems to become more interesting every time it is read, in that it is a man's real experience and not written merely for pay. I wish every beekeeper in the land could have a copy, and I can guarantee that they would be more than pleased with one.

In conclusion, let us all hope that another man like Quinby will help beekeepers as

much as he did. I know of only one monstrous invention yet to be thrust upon the world—artificial comb honey. Let us hope that some one will invent this and claim the \$1000 reward now offered by the A. I. Root Co. for the manufacture of a single section of comb honey which so closely resembles the original as to deceive the average person.

Springville, N. Y.

MOSES QUINBY

BY P. H. ELWOOD

When Mr. Elwood sent the photograph showing Mr. Quinby and his family, page 274, he enclosed a copy of an address that he delivered in 1876, saying that he would send a further article in a few days. As it was already late we feared that the article might not reach us in time, therefore we decided to use the address, to be on the safe side. The following article came just in time to be used in this number.—
Ed.

Whoever finds it difficult to obey the command "Love thy neighbor as thyself" may turn to the life of Moses Quinby for inspiration and example. The ruling passion of his life, inspired by a true brotherly love, was the betterment of others; and no estimate of his character can do him justice that does not fully recognize his life-long devotion to his fellow-man. He was possessed of the missionary spirit and was found in the front rank of any undertaking that promised to elevate mankind. In material things beekeeping was his theme; and for many years much of his time was spent gratuitously for the instruction of beekeepers, not only in the bee and agricultural journals, but in his modest St. Johnsville home, which might appropriately have been named the Quinby School of Apiculture, with classes for all grades. Captain Hetherington says, "Twice I was at his home in June, when I found there three from a distance to whom he was imparting instruction; in fact, his house was quite a hotel most of the time, with this difference—you could get no grog, neither could you pay a bill except by imparting to and helping others in the same generous spirit.

Not all, however, were willing to pay in this way. One man who came and stayed, and was particularly anxious to get all information that would be of help to him, said, when ready to go, "My neighbors will want to find out all I learned down here, but I won't tell them a thing. They won't be willing to pay a cent for it." Here the seed sown by a generous hand surely fell upon stony ground. The man, however, represented only a few of his visitors, nearly all of whom were appreciative, and

many of whom were leading men in bee culture, able and willing to give valuable ideas in exchange for the ripened experience of Mr. Quinby.

When Mr. Quinby commenced beekeeping bees were kept in box hives, and honey-getting was by the brimstone-pit, a murderous way unknown to many beekeepers of today, but so well described by the poet that it is given here.

Ah! see where, robbed and murdered in that pit,
Lies the still heaving hive, at evening snatched
Beneath the cloud of guilt-concealing night;
And, fixed o'er sulphur while not dreaming ill,
The happy people in their waxy cells
Sat tending public cares.
Sudden the dark, oppressive steam ascends,
And, used to milder scents, the tender race
By thousands tumble from their honied dome
Into a gulf of blue sulphurous flame.

—Thomson.

For the box hive he early substituted the movable-comb hive and glass surplus boxes. With these and the bellows smoker, which he originated, there was no longer need of the sulphur torch, for whatever honey was wanted could be taken without destroying or even angering the bees. Mr. Quinby unselishly took no patent on his smoker, preferring to give his invention to his fellow-beekeepers, taking the high moral stand since taken by the medical profession, that any valuable discovery or invention made by any one belongs not to him alone who made it, but to all alike for the benefit of humanity. No invention is born perfect, and some of the improvements on the Quinby smoker have been valuable. One inventor took the Quinby smoker, and, cutting off the connecting tube between the bellows and fire-box half an inch or more, had this missing half-inch patented. Then, denying

Mr. Q. and other makers the privilege of using the patent, he commenced the manufacture of the unpatented Quinby smoker, but with this slight omission. Because this small change made the Quinby smoker more efficient in holding fire the cut-off became a necessity; and because the principal or basic ideas of the invention had not been patented by Mr. Quinby it became comparatively easy to appropriate these ideas belonging to the public, and establish a monopoly. He attached his own name to the smoker, and for many years advertised it as the "original bee-smoker." But all attempts to deprive Mr. Quinby of the credit of being the originator of the bellows smoker have failed to impress well-posted beekeepers; and we read on page 263 of the *A B C of Bee Culture*, 1895, these words: "It is to the credit of Moses Quinby for first giving us a bellows bee-smoker."

Taking the Huber hive as a basis he invented a closed-end standing-frame hive unequaled for wintering, springing, and moving bees; and some of us think it unsurpassed for other purposes.

As an inventor, however, his fame will rest on his invention of the bellows smoker, undeniably the most useful implement in the apiary.

A full account of Mr. Quinby's experiments, and many of them were difficult and expensive, would fill a volume. Forty odd years ago the writer was at his place when he was attempting to induce early brood-rearing before placing the bees on their summer stands. He had twenty colonies in a special repository kept at a summer temperature by artificial heat. This was before the invention of thermostats or heat-controlling devices; and one night a warm high wind arose that so increased the draft of the fire and the temperature of the room that the whole twenty colonies were killed. Yet so possessed was he of the investigating spirit that, to get definite results, he would have repeated the experiment had not his friends dissuaded him from attempting it with the means at his command. He was a careful observer, and his conclusions could usually be depended upon.

It is not too much to say that Mr. Quinby knew more about American foul brood and its treatment and cure than any other beekeeper who ever lived. More than half a century ago, while yet using box hives, he met this deadly disease, and, unaided, he vanquished it by the method that in recent years has strangely been known as the Me-

Evoy plan. American foul brood, so far as now known, is a disease of the brood only, and was rightly called foul brood by Mr. Quinby.

We are able to give a picture of the Quinby family taken in front of their St. Johnsville home—Mr. and Mrs. Quinby, their son John W., their daughter Elizabeth, and their son-in-law, L. C. Root. Mr. Quinby died May 27, 1875, aged 65. Mrs. Quinby, known and highly esteemed by many beekeepers, outlived her husband 26 years, and died at the Root home in Stamford, Ct., in 1901. The son, Rev. John W. Quinby, was educated at Fairfield Seminary, Amherst College, and Harvard Divinity School, his education having been broken into by his service in the Civil War. Immediately after his graduation from the Divinity School he was installed as pastor of the Unitarian Church at Eastbridgewater, Mass., where he remained thirty years. He resigned while still in his prime, and while still doing most efficient work, because he was afraid he might stay until his usefulness was passed. He remained in the same town until he died, in 1911, in his 78th year. The daughter, Elizabeth Quinby, was married to Lyman C. Root in 1869, and they had two daughters—Dr. Stella Quinby Root, who, for the past eighteen years, has been in general practice in Stamford, Ct., and Kathryn Hildreth Root, who holds the responsible position of Supervisor of Home Economics in the Stamford public schools. Dr. Root is quite successful as a practitioner, and stands high in her profession as a skillful administrator of anaesthetics. Mrs. L. C. Root died in 1896 at the age of 59. She was a remarkable woman in many ways, and assisted her father and husband very materially in illustrating and rewriting their books. She was very skillful with her pencil, and many of the illustrations drawn directly from the object to be illustrated are from her hand. One in particular made in this way, the cut of bees and comb (see page 270), is regarded as one of the most accurate representations ever made, and has been widely copied in this and foreign countries.

Of the son-in-law, L. C. Root, nothing need be said to introduce him to the readers of *GLEANINGS*. As might be expected, both he and his daughters are widely identified with church and philanthropic work in Stamford. Mr. Root is well preserved, and now bids fair to rival Dr. Miller in longevity.

Starkville, N. Y.

THE QUINBY FEEDER

BY J. E. HAND

There have been so many requests for information regarding the Quinby feeder that we thought best to reprint a part of the article by Mr. Hand, which appeared in our Aug. 15th issue for 1907, page 1086. This feeder as used by Mr. Quinby sixty years ago is just as good now as it was then. Mr. Hand's description follows.—ED.

Perhaps the first thing to be considered in feeding back is the feeder. For several years we were handicapped in our operations because none of the feeders that were listed in any of the supply catalogs were of any account for the purpose, so we invented several of our own; and, although some of them were an improvement over the others, yet they were not entirely satisfactory.

Finally we found a feeder illustrated in "Mysteries in Beekeeping Explained" that was just what we wanted; and, although we have used it for more than ten years, we have not been able to improve it, and we are using it to-day just as Mr. Quinby did more than fifty years ago.

The feeder is a tin tray two inches deep, inclosed by a wooden frame of the same depth. The wooden frame is of the same width as the hive, and $2\frac{1}{2}$ inches longer, while the tin tray is the same length as the hive. This tray is pushed to the back end of the frame surrounding it, leaving a space of $2\frac{1}{2}$ inches in front for the bees to pass out and in the hive, and at the same time allows the tin tray to project beyond the hive at the back end for filling the feeders (see illustration). There is also a framework of slats, lengthwise of the feeder, and of the same depth, standing on edge about $\frac{3}{4}$ inch apart, for the bees to travel over while

working in the feeders, so that no bees will be drowned. The feeder rests square on the bottom-board, and the hive rests square on the feeder except the $2\frac{1}{2}$ inches at the back end, which is covered by a board. The

bees cannot get into the place where the feed is poured in, and the feed flows evenly under all parts of the hive, where it will be quickly taken up by the bees.

This feeder will hold six quarts; and after using it quite extensively for feeding back we do not hesitate to pronounce it by far the best one that has yet come to our notice, and we doubt if it can be improved.

HONEY AT THE PANAMA-CALIFORNIA EXPOSITION

Interesting Display in the San Joaquin Valley Building at San Diego

BY ALLEN HENRY WRIGHT

There is no doubt that many a blushing bride, on her wedding-trip, will declare the Panama-California Exposition, which opened in San Diego, California, on New Year's Day, "just too sweet for any thing," for it has many features which appeal to the romantic as well as the artistic, to the utilitarian as well as the amusing and interesting.

To beemen in particular, and to all those connected in any way with the great industry of making and marketing honey, there will be much of interest to be found in the building erected and filled by the eight counties of the San Joaquin Valley.

Here will be found a honey display, occupying a space about fifteen feet high by ten feet wide. At the top are the letters ALFALFA HONEY, each letter of which was used as a separate box, filled with artificial comb, and then placed in a hive, the bees doing the rest of the work of filling the comb with honey.

On either side of the display are panels containing pressed wild flowers, with bees above and about the blossoms. Combs of honey and jars of strained honey fill the spaces in the center and about the edges. All in all, the exhibit is one of the most pleasing and novel in the building, which contains hundreds of unique features.

San Joaquin Valley building at the Panama-California exposition, San Diego.

Elsewhere on the exposition grounds there is an exhibit of all kinds of equipment for the bee-culturist, including the latest de-

vices and paraphernalia for conducting the business on a paying scale.

San Diego, Cal.

THE OLD FOLK IN THE BEE HOME

BY J. E. JOHNSON

Since the writer of this article had a little success in beekeeping, his neighbors have become interested; and now within five miles of the original yard that started the fever there are as many as one thousand colonies. These friendly would-be beekeepers often drop in and talk shop. They are very much interested in fixtures. They talk hives and frames and smokers and supply-dealers, but there is not much disposition to talk bees. These good friends have been reminded time and again that success is not tied up in the subject of fixtures, great as is the importance of having fixtures right and standard.

Recently a new man in the bee business spent a whole week going over his yard examining his colonies and feeding nearly every one. He realizes now that this work should have been done last fall; but the bees had to be fed or would die, and so he kept on feeding with the temperature down to and below freezing.

How few beekeepers stop to think that all the bees are now old, and living in their declining years! Last October they were strong and young, able to do a woman's work, but now they are getting old and

feeble. Many of them have gray hairs, some are crippled up with the rheumatism, and hardly able to get about. But the family must be cared for. Water must be brought, and the home must be kept warm. And all this work must be done by these old people in the bee home. There is no young person about to hustle around early and do the roughest work.

With this idea in mind, how important it is to treat these old people in a way to make it as easy as possible on them! For the next few weeks they face the hardest battle of life. If they can hold together until the warm days come, then soon they will have help, but all the work must now fall upon their old shoulders.

If this idea could be well drilled into the young beekeeper's head he would not feed too much raw syrup to the old bees and make them work it over, and store it again in their combs. He would not require them to carry water half a mile. He would not ask them to stay in a hive where the roof was leaky, and air currents constantly cooling off the home.

Mt. Airy, N. C.

HOW FAR DO BEES FLY?

BY J. A. HEBERLE, B. S.

Much has been written about this subject. Opinions differ greatly, as might be expected, because the solution can be only an approximation. The distance varies with the season, the time of day, the temperature, and also with the plants that supply the nectar and pollen. It is influenced by the configuration of the surrounding country.

The editor of the *Western Honey Bee* says: "How far bees fly and store honey to a profit depends on two things: First, the plant they are to get it from; second, whether or not intervening plants have led the bees to the field." [G. M. Doolittle has said the same.—H.] He has seen the bees work on mesquite where the nearest bushes were a mile and a half, and the bulk of the yard seemed to be going about two miles, with the result that scales under an average hive showed nine pounds gain. [That would be a record around here.—H.] He further said bees will make a good gain from a good field of alfalfa a mile distant, and he would count on a good deal of surplus from one and a half miles. Three years ago one of his neighbors had a yard two miles from the only orchard that was sprayed, and the bees carried enough arsenate of lead from the fruit-bloom at that distance to kill some of the colonies outright.

Geo. L. Emerson, in the *Western Honey Bee*, says: "For some years we have had our apiary No. 8 in a location that is over six miles from an orange-orchard, but these bees seem to gather orange honey as fast as bees nearer the trees when the weather is warm and favorable."

J. D. Bixby, on the same subject, said that he knows of an apiary in Iowa which is six miles from the nearest basswood-tree, and eight miles from any larger range of basswood. In any year that the basswood has yielded nectar, this yard has stored thousands of pounds of basswood honey. His personal knowledge of this yard extends over 45 years. He observed last year that numbers of golden Italians were working on white sage on a 1500-foot hilltop four miles from the nearest yard containing such stock.

Mr. Goeken, who read my translation of these items in which they say that bees would fly for orange and basswood nectar six to eight miles, writes in the *Bw. Ctrblatt* that he doubts that any bees in Germany—the blacks, Carniolans, or Italians, would fly that far for nectar, and added that, if these distances (six to eight miles) are

actually made by the bees it would be well to introduce them in Germany.

In his extended practice he found that, if bees were moved, during a honey-flow, a distance of one and a half to two miles, they would not fly back to the old stand.

According to his observations bees would gather nectar at a distance of $1\frac{1}{4}$ to $1\frac{1}{2}$ miles in any direction unless they are led further by an extended field of nectar-yielding plants. He asks any German beekeeper who has observed that bees gather nectar at such great distances as above cited to have such observations published.

A month later Heinrich Theen writes in the same journal that, generally speaking, he agrees with Goeken that bees usually do not forage much over $1\frac{1}{4}$ to $1\frac{1}{2}$ miles distant.

About seventeen years ago he was the only beekeeper who had Italians in that neighborhood. Seldom could he find his yellow bees further than $1\frac{7}{8}$ miles. However, his bees would visit a rape-field when the weather was real fine, at a distance of $2\frac{1}{2}$ to 3 miles.

At a distance of $1\frac{7}{8}$ miles from his apiary there is a heath of some 500 acres. In a dry season considerable honey is gathered by the bees near this field, while his bees visit the field of heather very little. He can find but a few cells of this honey in his hives.

BEES FLY FIVE MILES OVER WATER.

Mr. Theen states further, that on his side of the water the farmers have quit planting rape, but on the other (Danish) side there are still large fields of rape. From an elevated place some little distance from his side of the shore the rape-fields when in bloom can be clearly seen. At a village a quarter of a mile from the shore there are several small apiaries; and when the rape-fields yield nectar the bees fly in large numbers across the water—a distance of five miles. A few of the bees succeed in returning with a load, but the most find their death in the cold water. The fishers on the water's edge say that bees often take a rest on their boats when they pass the line of flight of the bees. Usually the bees fly very low on their return across the water, and a gust of wind drowns them by the hundreds. If the wind blows from the opposite side, lots of dead bees are washed ashore. He thinks the bees are misjudging the distance across the water, else they

would not undertake a trip which in windy weather means sure death to them.

So far as I can see from the writings of various authors it was generally believed that bees would cross only short distances over water; but here is a case that shows that assumptions, though long believed, may

be erroneous. By a long-distance flight to the source of nectar the loss of time consumed by the flight is not of so much importance as the wearing-out of the bees and the losses incident to long-distance flying.

Kempton, Bavaria, Germany.

A HOUSE-APIARY AND A SCHEME FOR KEEPING ANTS AWAY FROM THE BUILDING

BY E. R. ROOT

When we stopped off at Delray to visit Charley Repp, where the Repp brothers, of apple-growing fame, have their Florida farm on which they grow cucumbers by the earload I asked if there were any bees in the vicinity, and was told there was a man who had quite a house-apiary not a great

Hoeness. He owned a couple of town lots, all the bees there, and had been gone for two years. He used a sort of long German frame, very deep, and each colony was in a compartment by itself. Some of them were dead, but others were very much alive, as we found when we tried to "investigate."

But the thing that interested me particularly was a way to provide against the depredations of ants, which are very troublesome in those parts. The accompanying illustration, Fig. 2, will show one of the corner foundations surrounded by a concrete box to hold water. Every time it rains these boxes get filled with water, so, of course, the ants do not have very much chance to get into the building.

Not much was known of this Mr. Hoeness, and it was thought he had gone to Michigan. His near-

est neighbor is Mr. J. W. Lamb, and possibly he may know where he is by this time if he has not returned.

Of course bees are very necessary for growing cucumbers. No bees, no cucumbers. That has been proven over and over again.

FIG. 1.—George Hoeness' house-apiary near Delray, Florida.

distance away. Of course I said I should like to see it, and, sure enough, he had quite a building. I took a picture of it as shown in Fig. 1.

No one seemed to know very much about the owner, except that his name was George

ARKANSAS RETROSPECTS AND PROSPECTS

BY C. W. RIGGS

Last year was one of the worst known in the history of this section, and bees as a general thing did not make honey enough to winter. I fed from the outside along in November and December; and on January

11, as all the bees were flying nicely, I went through my yard of twenty-six colonies and equalized the stores. I had five or six small nuclei that I thought it hardly possible to get through the winter, but to-

day (Feb. 16) all are flying, and upon examination seem to be doing nicely.

The maples are in bloom, and each colony (and nucleus as well) is as busy as can be, starting in the spring honey-gathering. We do not need to pack the hives in this section of the country, as we have only from four to ten weeks with, say, an average of six or seven weeks of any thing that might be

called winter. But only a few days of this is actual winter as known in the North.

Arkansas, generally speaking, is a good state for bees. In fact, the woods are full of them—more in the woods than in yards; but with the advent of sweet clover, which is coming into its own, I think she may take place as one of the leading honey states at no distant day.

Greenland, Ark.

TAKING BEES FROM A CHURCH

BY W. J. WOOLLEY, JR.

The village of Sedgeberrow is an old-time hamlet of about 300 inhabitants. It lies under the shadow of the Cotswold Hills, and is principally given over to farming and gardening. The church is a strong stone-built edifice with stone roof (not tiles).

Between the ceiling and the roof seven colonies of bees had built their homes. The old inhabitants stated that they had been there for 30 years for certain, and perhaps more. But the vicar of the church let them go on the same old way till this year, when they began to be a little more venture-some, and one day they swarmed while the service was being held, and settled inside the church. So the vicar decided that they all should be ejected from the holy place, pack and baggage.

He gave the order to a local firm of builders to clear the bees, honey, and comb from the building. They sent two bricklayers over from Evesham to investigate and eject the bees if possible. The men started bravely, and began to take the stone roof off the place where the bees were seen to fly from; but in less than half an hour they had to beat a hasty retreat down the ladders to the ground.

After a conflag they decided to leave the work and get some one else to do it. So they decided to come to the local expert and ask me if I would undertake the job for them. After visiting the church I offered to do the work of clearing the bees and honey out if

I had the greater part of the honey and the bees. As they could not do it themselves they agreed.

The roof is forty feet from the ground,

FIG. 2.—Hoeness' scheme to prevent ants from getting into the house-apiary.

and the bees had built their home at the junction of the wall and the roof between the rafters, and between the ceiling and roof. After a good smoking, with the help of the bricklayers I proceeded to take the stone roof off over the nest, and found a very large nest in the form of a triangle. The longest combs were over three feet long, and the nest was a yard wide at the widest part. The majority of the combs were as black as ink, and were built like the combs in a skep or box. Some were straight, some crooked, and some braced together in all sorts of ways. After two days' work we three cleared the bees and honey out from the building. I did the work with the two bricklayers waiting on me, and carrying the

stones and the honey down the ladder to the bottom. It caused quite a commotion in the village, most of the inhabitants coming to get a look from a respectable distance. After we had finished we found we had about 260 lbs. of honey besides the bees. My share of the loot was 160 lbs. of honey; and after straining it I had 10 lbs. of wax. The other 100 lbs. was divided between the two bricklayers and the foreman, besides sweetening the boys who used to come and say, "Master, give us a bit of honey, please."

But what I noticed principally was that, although the combs were in some cases so

old, there was no sign of foul brood or any other disease. The bees were very strong lots. Of course I got my share of stings on my hands and arms, but that did not matter. I have had so many that my system has become used to stings. The other men got off very light indeed. Of course we all wore veils, which I provided. It took the bricklayers two more days' work to replace the roof after we had got the bees and honey out. It turned out a very pleasant and profitable work for me, and I should be glad of a few more jobs like it.

Evesham, Worcestershire, Eng.

MAKING GOOD WITH NINE COLONIES

BY H. N. WAGNER

The way I got into the bee business was very simple. A swarm had taken up its home in the corner of our house. So long as the bees were willing to attend strictly to their business they were left alone; but they took a notion that the whole house and yard was theirs. My wife and little boys were stung so often that at last they simply forced the man of the house to act. The bees had to be taken out. I read an advertisement in the local paper that Stoheman, the beeman, would take bees from houses. I found him a rather meek sort of fellow. In talking with him I discovered that he taught a class in the Methodist Sunday-school. This made me especially anxious to secure his services in getting out the bees, for I had often heard when a boy that bees will not sting a truthful or an honest man. I wanted to prove this old saying. I knew a teacher in a Methodist Sunday-school must be honest, and reasonably truthful.

On the day appointed, John with his tools and hives came out to do the work. He was to take out the bees and hive them, and I was to pay at the rate of \$5.00 a day. I was to help.

After the side of the house was opened, I stood back and watched John. I noticed that the bees were stinging him. I watched his lips, but I did not detect by them that he was swearing "under his breath." I hated to doubt the old saying, nor did I want to doubt John's honesty. I had some doubt about the truth of the saying within a few minutes, as I took a hand in the work and received several stings. I believe most old sayings are not quite true.

When we finished the day's work we had four colonies in hives. We took two from a neighbor's house; and, a few days before,

a stray swarm came along and settled on a sage-bush which I had put in a box.

I now felt that I had been born into the beekeeper's guild. John had gone home with a check for his labor and hives, and the tools which he said I needed. I noticed when he left he seemed to have an expression upon his face which said, "I have my pay for my work. You will get your experience as the days pass."

The bees were put into hives about the 10th of July. In October I had a surplus in large extracting-frames of almost 500 lbs. which I sold to people for ten cents a pound in the frames. After keeping honey for our own use I sold a little over \$40 worth to my friends. I had enjoyed taking care of the bees; and when the wife saw the money coming in she felt somewhat more charitable toward them. But they had stung her so much she was very sick from the effects of the stings, and has not learned to love them. She even claims that I, like all beemen, have gone a little "off my base."

Since I did not know any thing about wintering bees I read some of the methods given in the bee literature. I just packed them away in leaves, leaving part of the front of the hive exposed. When spring came I found one of my four dead. I opened the second season with three strong colonies. I made an increase of four. About the middle of the summer I saw John, my old friend who always has an eye to business. He knew I had a bad case of bee-fever. In his travels he had picked up nine boxes with a few bees in each box. He said, "I will sell you those nine colonies for \$11. I bit quickly. I took them home, and only six of them had any brood. I had also bought from my beeman ten ten-frame

hives and transferred the bees from the boxes into the ten-frame hives, making six colonies of them. When fall came they had filled the brood-chamber, and some had made some surplus. When I took off my honey in the fall I had a market for all that I had in the large extracting-frames. I found I had about 1200 lbs., for which I received ten cents a pound. I now had thirteen to winter, and successfully tried the same plan as the year before.

In May, while I was away from home for several weeks, there was much cold wet weather; and when I came back I found that four of the colonies had been robbed. There remained only a few bees in each hive. I placed them all in one hive and gave them a frame of larvæ. They went to work and raised a queen; and while they produced no surplus they had plenty for winter. By fall I had seventeen colonies.

A NOVEL SCHEME FOR PRODUCING COMB HONEY.

The past summer I produced nothing but comb honey in sections. My friend the beeman told me that I would have trouble in getting the bees to work in sections, and that I had better stay by my old method. But I had already ordered my supplies for running for comb honey. John said if I made twenty-five cases I would do well. After my robbing experience I had nine

colonies. I knew that any sensible bee would go into an extracting-super when the super is filled with full sheets of foundation. I said, "Why not fill the section-holders with full sheets of foundation?" I did. Then I took my sections, ripping them to make two sections of one. Then when the section-holders were about half filled with drawn comb I took the press which I had made, placed four of the narrow sections I had ripped on each side of the section-holder, pressed them down solid, and then put the section-holder back into the super to await results. The bees seemed to be struck with the scheme, and just went at it and filled them. I tried this upon each colony, and without exception they went into the super and worked fine.

When I took the sections off there was a line where the two halves of the section met. Over this I placed a strip of white paper, and I had a strong and clean section. I used this scheme to get the bees started to work. I had no extracting to do.

I had an order for 500 lbs. of honey in large frames. I produced this and almost 1300 finished sections from my little yard of nine, spring count, after four had been robbed out.

So much for my bee trials and joys. I still have the fever.

Blackfoot, Idaho.

EASTERN NEW YORK BEEKEEPERS' ASSOCIATION

BY S. DAVENPORT

The seventh annual convention of the Eastern New York Beekeepers' Association was held at the City Hall, Albany, Dec. 30, 1914. The unfavorable season for honey production during the past year evidently had a depressing influence on the beekeepers of this part of the state, as was indicated by the slim attendance at this meeting. The association has never before had so few members in attendance; but those who were present were all live wires, and what was lacking in numbers was amply made up in the very interesting sessions.

After the report of the treasurer, showing a handsome balance in the treasury, the president made his report as delegate to the joint convention of horticulturists and beekeepers held at Syracuse during fair week. The president also gave a long and interesting report of the annual convention of the State Association of Beekeepers' Societies.

Charles Stewart, state bee inspector, at the suggestion of the president, repeated his remarks given at the annual meeting of

the State Association on the subject of feeding back and feeders.

After some remarks by the secretary in appreciation of the several persons mentioned, who have shown much interest in the association and its objects, they were made honorary members as follows: Chas. Stewart, state bee inspector, Sammons-ville, N. Y.; Dr. G. G. Atwood, horticulturist of the State Agricultural Department, Albany, N. Y.; Dr. Burton N. Gates, apian professor at the Massachusetts Agricultural College, Amherst, Mass.; Rev. I. V. Lobdell, Middleport, N. Y.; Audubon Johnson, Simi, Cal. The three last-mentioned gentlemen were formerly active and valued members of the association.

A vote of thanks was given to the State Agricultural Department for the assistance of the state bee inspectors given to the beekeeping industry by their work and their attendance at the conventions of the beekeepers of the state.

The subject of advertising honey to create

an increased demand for it was considered, but no action was taken.

A committee nominated the following members for a board of officers, all of whom were unanimously elected. President, W. D. Wright, Altamont; first vice-president, Charles N. Hays, Brookview; second vice-president, Irving O. Cross, Hoosack Falls; secretary, S. Davenport, Indian Fields; treasurer, I. J. Stringham, New York.

A summer field-day meet and demonstration was suggested, and received much fa-

vorable consideration. The president and I. J. Stringham were elected a committee to superintend the matter and make it a success. The meet will be held at the home apiary of the president at Altamont, some time in July.

Two interesting letters from Audubon Johnson, Simi, Cal., were read by the secretary, and received much appreciation.

President W. D. Wright and W. D. West were elected delegates to attend the next annual convention of the State Association. Indian Fields, N. Y.

DIVIDING COLONIES BEFORE THE SURPLUS HONEY-FLOW

BY R. F. HOLTERMANN

When we undertake to combat an idea we ought to make quite sure that the man we connect with that idea holds it, else we are apt to find that we are aiming at an imaginary target.

I want to endorse fully what Dr. Miller has stated in GLEANINGS in effect, that, with a white or alsike clover-flow prospect, it is unwise to divide colonies before that flow. For quite a number of years, now in the distant past, I had the management of a bee-supply business; and let me say in an aside that my experience in that line, knowing what the net profits were from year to year, has made me quite willing to let the supply-dealer have what he can make out of that business; but during that experience, and since, I have seen that one of the rocks upon which many a beginner in the bee-keeping business makes shipwreck is the intense desire for increase. It is like the case of the hen to which the owner gave about thirty eggs to sit on. When asked why he gave her so many he said, "I just wanted to see the old fool spread herself." I am not relating this story for fun nor with the expectation that the readers of GLEANINGS have not heard it before, but because it is applicable to the subject in hand. We as beginners want to spread ourselves and we often do it to an extent that we undertake more than we are able to bring to a successful issue.

There may be occasions when increase is desirable, sacrificing the honey crop; but as a rule, the first few years at least, it is better to make a very moderate increase and secure a honey crop.

On page 137, Feb. 15, Dr. Miller points out the difference between expecting a honey-flow from which one can reasonably expect a surplus, beginning May 27, and

when such a flow begins 27 days later. He stated that he had known the white-clover harvest to be over by July 4. I too have had such an experience. I venture to say that many a beekeeper has had no surplus honey, or very little, from one colony when he might have had 50 lbs. to the colony if these colonies had been in prime condition at the beginning of the honey-flow. I know what I am talking about, because I have had personal experience along that line. Who, unless he has equalized colonies, or unless he has a very limited number of colonies, has not had in the apiary some which have given about one superful of honey before or by the time another needed a super at all? In such a case as Dr. Miller states, if the flow should be short, or if it should cease at the time specified above, one can not see the great difference in yield. It is all very well for people to talk about having every colony practically the same. In rare instances it may be so; but more people judge their own with partial eyes, and I fancy I would require a microscope to find the percentage having the apiary in such condition.

My practice, so far as the magnitude of my operations will allow, is to build up the bees so that they will occupy with brood, bees, pollen, and honey the twelve-frame brood-chamber. I then take out of the strongest colonies several combs of brood as nearly mature as I can find it, and give these to colonies which will not quite reach that stage by the time the surplus flow comes on. This practically makes them full colonies also, and so in this way I get the largest number of full colonies for surplus honey. Every bee emerging from the transferred combs is in a full worker colony, and the brood developed in the frames put into the strong colonies will be much

greater than that which would have developed in the weaker colonies.

In the place of the combs of brood taken out of the full colonies I insert frames with foundation unless I have all the comb I want, for no better place could be found for this work. If I put in drawn comb I seek to use that which has been used in the brood-chambers.

Let me say here that there are, perhaps, many beekeepers who put combs into brood-chambers built on sheets of foundation which have absolutely no business in a brood-chamber. If the foundation stretches, the comb built thereon is unsuitable for brood-rearing. The queen dislikes it, and it is a hindrance to the rapid development of brood. If comb has been in the super with wide spacing, as is generally the case, making it a deep cell, it is objectionable, and the bees have to remove a portion of the side wall before it is useful for brood. Such a comb should be thinned down with a sharp knife before using in a brood-chamber.

It is a very difficult problem with me what to do in case the brood-chamber is crowded and a good honey-flow is on. Generally when a comb of brood is taken out and we insert an empty comb the bees are more than likely to fill it with honey; and where that is recommended I sometimes wonder if the beekeeper has tried it very much; or, if so, whether he had time to note the result; or if the colony was really a

strong one, or if the honey-flow was really a good one. This may be an honest case where the nature of the honey-flow may make a difference in results.

After trying the Alexander method of increase, if by that is meant putting a weak colony on top of a strong one, I have not found that method as advantageous as the way I have described. It appears to me that the weak colony must be built up at the expense of the stronger; and until the stronger has more bees, heat, working force, and the queen has reached her limit in egg production, I see no gain in giving them the added responsibility. P. C. Chadwick well states, page 139, "I infer that Dr. Miller believes in one large force of bees to a hive, rather than a slightly greater number divided into two hives, and in this I believe he is entirely right." So say I.

For years I had the bees on clover ground during the early part of the summer, and about Aug. 1 I moved them to buckwheat. I did not then consider it wise to risk a portion of the white-honey crop with the object of being the gainer on the dark flow. There may not be any dark honey, and it is worth less per pound.

Increasing during the honey-flow, or before a prospective flow, is in my estimation unwise unless one has the practical experience to warrant keeping more bees and if he cannot purchase them at prevailing prices.

Brantford, Canada.

HOW I IMBED WIRES IN FOUNDATION

BY A. W. SMITH

Perhaps some might like the way I fasten foundation in wired frames. It seems that Miss Wilson has been using a somewhat similar method, but I had not the slightest idea she or any one else imbedded wire this way. I worked out the problem alone four or five years ago, and with the help of a boy at fifty cents a day I securely fastened 150 pounds of medium brood foundation in wired frames in ten hours, and found this plan better than other methods I had used.

Our method is, in brief, as follows: Make a coverless box 4 inches deep, about 8 inches longer than the top-bar of the frames, and $\frac{1}{2}$ inch wider than the outside width of the frame. On the outside of the box at the upper edges fasten thin strips about $\frac{3}{8}$ inch higher than the sides of the box, these to prevent the frame from moving sidewise when pushed along on the edges of the box.

Then secure four little spirit-lamps holding perhaps two ounces of wood alcohol each, and trim their round wicks so they come to a point.

Fill and place the lamps near the center of the box in such a position that the blaze nearly touches the wire of the frames when slid along on the edge of the box. Pressing a piece of pasteboard against a sheet of foundation placed on the wires in the frames, slide the whole arrangement over the lamp blaze and see how quickly and neatly the four wires have been imbedded.

I do not use groove and wedge top-bars, and have several reasons why I would not use them as a gift. I fasten the foundation in the top-bar with melted wax, holding the frame nearly perpendicular so that the hot wax will not melt through the foundation.

Birmingham, Mich.

BEGINNING WITH BEES HALF A CENTURY AGO

BY WILLIAM P. HENDERSON

Before I arrived at manhood I dreamed I would have a home of my own, with plenty of milk and honey—two articles of diet I was fond of. So, soon after my marriage a small place was purchased; then a cow and calf, and a hive of bees. But knowing nothing about bees, except that they make honey, and can sting, I learned from the farmer of whom a hive of bees was purchased, that at a certain time of the year, "corn-tasseling" time, after dark I was to tie a bed-sheet around the bottom of the hive to make a bag, pry off the top of the gum, and cut out the honey down to the cross-sticks in the middle of the hive, having previously prepared rolls of old cotton rags with which to smoke the bees off the comb.

About this time, which was more than fifty years ago, in looking over a catalog of books for sale my eyes fell upon "The Mysteries of Beekeeping Explained" by M. Quinby, St. Johnsville, N. Y. Up to that time, if my memory serves me, I was ignorant of any literature on the subject of the management of bees.

"Mysteries of Beekeeping Explained"—that's what I want to learn. It is all a mystery to me, except what was told me by

some old bee-owners whose advice and theories, as I afterward learned, were upset by Mr. Quinby.

The book was ordered, received, read and reread, and frequently referred to afterward for directions in manipulating my bees.

The work of Mr. Huish, F. R. S., an English author (full of errors), and other books on bees were afterward purchased; but in a practical way they were not the equal of that of Mr. Quinby's.

From that time on I went far ahead of the old timers in the production of honey and growth in numbers of my colonies.

Tampa, Fla.

[In the late 70's and early 80's, Mr. W. P. Henderson, then of Murfreesboro, Tenn., was one of the most prominent queen-breeders of the country, and, incidentally, a spicy writer along his line of work. He made one of the best collections of old bee-books ever known in America, being second, probably, only to that of Thomas Wm. Cowan in London. These books were transferred to us in 1892, and were reviewed in detail the following year. Any thing from his pen is worth reading.—Ed.]

A. I. ROOT

BY GRACE ALLEN

Alone I sing so slight a song, I'm like a single bee,
Her humming all unnoticed in the blossoms of the tree;
But when the petals quiver and the fragrant air is stirred
By murmurs of a thousand bees, ah! then the song is heard.
So, beemen near and beemen far, come swell my simple song,
And let it surge from sea to sea and echo true and long:
"The world will be a fairer, cleaner, better place for all
When more men live like A. I. Root and let their souls grow tall."

Through all his years he's stood for right, for honesty and truth,
And see him now, in autumn time, as eager as a youth
To fight the evils of to-day, and in this pulsing Now
To meet new issues and new hopes with forward-fronting brow.
So, beemen near and beemen far, come join in my refrain,
And sweep the hearty echoes over mountain-top and plain:
"The world will be more like the place to which our dreams have clung
When men grow old like A. I. Root by simply staying young."

We love his little stories and the happy life they mean,
That first stray swarm, the windmill days, the chickens and dasheen,
The faith and works, the lesson learned, the earnest, hopeful prayer,
And how he helped one brother here, another brother there.
So join with me, O beefolk all, and let the echoes ring—
We're standing upright through the land as from our hearts we sing:
"The world is finer, sweeter, and God's Kingdom seems more near,
Because a man named A. I. Root is living with us here,"

Heads of Grain from Different Fields

The Backlot Buzzer

Sometimes it's a question which has the best-laid plans for the coming season—the boss or the bees themselves.

Has Never Found Foul Brood in Trees

I have been a bee-hunter ever since I was large enough to look up a tree, and my father was one before me. I always find from five to ten trees every year, and I have wondered why bees in a tree never have foul brood.

Last summer I helped to cut six trees on Fort Lewis Mountain. Making a good examination for foul brood I found every bee perfectly healthy, and the combs showed no signs of a bad cell. The reason that I am giving special attention to foul brood is that it cleaned up an apiary of a hundred colonies one or two miles from the mountain, and several absconding swarms have left this yard.

Just as with Ernest Webb, page 950, Dec. 1, it seems to me that when a swarm leaves a diseased hive and goes to the tree it would have the disease just the same as if it were in a hive. But the only foul thing I ever saw in a bee-tree was a blacksnake 6 feet 9 inches long. Father and I cut a bee-tree a year ago last summer. We found a snake among the bees, and there was not a single bit of honey in the comb. The bees seemed to have made friends with the snake, and did not try to sting it at all. The combs were five feet long.

Roanoke, Va.

HENRY S. BOHON.

[We see no reason why a colony in a tree might not have diseased brood. In fact, if we are not mistaken disease has already been found in trees.—Ed.]

Cyaniding the Ants

I was somewhat amused at the article by E. S. Miles, entitled "Fighting the Ant Invader," and wondered that a man should use a "barrel of coal

oil" to kill a few ants when for half a dollar he could kill all the ants on a ten-acre field. Here is a simple remedy:

Take one pound of cyanide of potassium and dissolve it in five gallons of cold water. Take a small can and go to each mound where the ants are, and pour about two or three tablespoonfuls of the liquor in each hole. In about four or five days, when a few more eggs hatch, repeat the operation again. It's good-by to the ants. Should any more eggs hatch, repeat the dose a third time. I have had some trouble along the same line, and find this remedy will overcome the pests completely. Strict care should be exercised in handling this remedy, as it is very poisonous.

Prescott, Ariz.

DAVID MILLER.

Too Many Supers Hinder the Introduction of a Queen

D. E. Lhommedieu is wrong on page 125, Feb. 1, in regard to the Miller method of introducing queens. Mr. Miller said that queens should not be introduced until the colony has quieted down from the overhauling in removing the old queen. This takes from four to six hours; and to try to introduce before is to invite disaster. Queens can be introduced from that time until they may have laying workers.

I think the cause of Dr. Miller's failure in introducing was the number of supers he had. If two or three supers are on the hive, it is impossible to get the whole hive full of smoke in blowing it in at the entrance. One or two puffs should be blown between the supers, and no more should be on than the bees can fill completely so they will not be driven up out of the brood-chamber.

Grosvenordale, Ct.

ERNEST RYANT.

How to Avoid Loss through Aster Honey

I can testify from experience to the truth of the statement, page 136, February 15, that aster honey gives bees dysentery. This locality is full of aster flowers, mostly white and brown, and they keep on blooming until the frosts kill them. They yield quite a quantity of honey.

When, thirty years ago, I began keeping bees, studying the A B C and subscribing for GLEANINGS, I followed their advice closely. I packed my bees for winter never later than the 15th or 20th of September. About that time the aster began to bloom; and as a result my bees had their hives full of aster honey, and most of it was uncapped for winter. I lost many, mostly by dysentery—sometimes 50 or 60 per cent.

I finally discovered the trouble, and now I never pack my bees until the aster honey-flow is over. Last fall I did not have a hive packed before November 1, and a year ago I was just done with it when the blizzard set in on the 9th of November. My aim is to get as much aster honey out of the hive as I possibly can, and as a result my winter losses are very small.

Port Clinton, O.

JULIUS JOHANNSEN.

Who Cares What a Section Weighs?

In reasonable years like the last, we can produce a very fine grade of comb honey here, mostly from wild prairie flowers, mesquite, and catclaw; but I think the government requirement as to having the weight stamped on each section is too severe to allow either me or any one else in this country engaging very exclusively in the production of comb honey. A comb of honey should sell on its looks,

like a watermelon or orange, or any kind of individual fruit or luxury, not by its weight. There is not one purchaser in 500 who cares whether the comb of honey he buys weighs 14 or 16 oz. so long as it appeals to his fancy in looks and flavor; so, why should we beekeepers be hampered with such an unreasonable ruling when the public can see what they are buying before they buy it. Unless something is done to have this regulation withdrawn I fear that comb honey will be even a scarcer luxury on the market of 1916 than it is now.

BASIL C. CAIRNS.

Few Swarmed Out After All

I see that Dr. Miller says, page 137, Feb. 15, as to my plan what to do when a swarm issues, that he would expect them to swarm again in twenty-four hours. I treated twenty-seven colonies that way in 1914, killing cells and taking four or five frames of brood, and only two swarmed out the next day. I had fifty queen-cells, although we had a rather poor season in 1914.

The colonies treated in this way all gave some surplus, from 35 to 50 sections of comb honey, while the swarms that were hived on full sheets of foundation gave ten to twenty sections, and some not any. In using this plan I think it best to put the brood in one side, as they will work in the sections sooner.

I am going to use this plan in 1915, and will report what success I have.

JAMES G. BENSON.

Bees Working on Red Clover

My bees are common hybrids, but last summer they worked on the second crop of red clover. While they stored but little or no honey, yet the hives increased in weight very much during the time red clover was in bloom; and if it had not been for red clover we would have had to feed in midsummer, as there was no white-clover honey, and the hives were very light August 1.

Some 25 years ago, when first coming on this farm I bought a colony of bees which died the first winter. I let the hive remain on its stand, and the second summer a stray swarm took possession, and my present stock of bees is from this stray swarm. I suppose that my bees are not better than hybrids at most, for, so far as I know, we have only one man for many miles around who has ever introduced Italian queens, and he introduced only one or two at most. At different times I have noticed my bees on red clover; but not up till last year did they get much nectar. Last year the hives were very light when the second crop of red clover began to bloom. I noticed that the bees were hustling out early in the morning, and working all day during August. In spite of the fact that we were having a very severe drouth. At first I could not tell the source from which they were gathering their stores; but I finally traced them to the red-clover fields, where I found many of them working on the red-clover bloom. And I know further that the hives increased very materially in weight during this August drouth while the bees were working on the red clover. We had good July rains that gave the second crop of red clover a good start, so that we had a good growth of stalk and head. It was very hot and dry in August when the clover was blooming.

Mendon, Mo., Nov. 2.

NATHAN CLAIRE.

South Winds Diminish the Honey Crop

Much is said about the shortage in the honey crop last year, and the blame appears to be laid to dry weather. If you have ever rustled sap in a sugar-camp you have learned that south winds dry the flow of sap. I have noticed that, when the prevail-

ing winds are southerly, the bees gather but little nectar. I have noticed this for a number of years. Here in northern-central Iowa the winds were mostly from a southern direction last summer, and our crop of honey was light. In 1913 it was almost as dry; but we had very little south wind, and therefore a bounteous crop of nectar.

Moorland, Iowa, Oct. 5.

UNCLE JOE.

Aster Honey has Done No Harm So Far

Thinking perhaps you would like to hear how bees are wintering in northern Michigan, where the mercury often drops down to 40 below, I will say I placed 59 colonies into winter quarters (in cases out of doors), and to-day, Feb. 22, every colony took a nice flight, and seems as strong in bees as when placed away. I tell you it made me feel pretty good to see them out so nice. Some of them had flown before, where they were back in the brush, and were more favored with the sun.

I was afraid of aster honey, as much of it was not sealed.

Mio, Mich.

JOHN A. STEVENS.

White Clover Poor because of Drouth Last Year

Honey prospects in this locality are very poor for this season. In my inspection last year I traveled all over the western part of this state, and found very little white clover started, on account of dry weather. Some places have considerable sweet clover, and there will be some honey-flow in localities along rivers; but generally the prospects are poor.

Most of the bees I inspected last season were short of stores, and weak in bees; and unless they were fed and protected there is sure to be a heavy winter loss.

Altona, Ill., Feb. 28.

W. B. MOORE.

The Farmer a Beekeeper

As to farmers keeping bees, p. 81, Jan. 15, I should say if there are none of the contagious diseases in the neighborhood every farmer should by all means have one or more stands. They require but little care, and are a diversion and added interest to him, and an education to the children, besides being the source of a delightful addition to the bill of fare of the home.

Where the contagious bee diseases are prevalent, however, I consider it utterly useless if not a crime against neighboring beekeepers, unless the farmer intends to turn beekeeper, or have the bees looked after by some one who is a beekeeper.

Carthage, Mo.

B. C. AUTEN.

Oregon Basks in Sunshine

Bees are now working on chickweed, crocus, and pussy willows when the weather permits. People are playing croquet out of doors. There has been no snow this winter, and the lowest temperature was 15 degrees. A brood of nine chicks, hatched about Feb. 1, have spent the greater part of the time out of doors, and all are alive and happy, notwithstanding Oregon is "dry."

Forest Grove, Ore., March 2.

S. T. WALKER.

Reports Successful Wintering

Bees have wintered well, and are in excellent condition at this time. A heavy aster flow last fall made plenty of stores for winter, and spring feeding will be unnecessary. Although it is early to predict, the clovers do not look promising here.

OUR HOMES

Editor

Choose ye this day whom ye will serve.—JOSH. 24:15.

His sons made themselves vile, and he restrained them not.—I. SAM. 1:13.

Honor thy father and mother, which is the first commandment with promise; that it may be well with thee, and that thou mayest live long in the earth.—EXH. 6:2, 3.

I was brought up by godly parents, and attended Sunday-school regularly until I was toward a dozen years old. We lived in a small town; and when I approached my teens I got in with a crowd that made light of religion, and soon began to think I was getting *too old* to keep on with the children, notwithstanding the efforts of my parents, especially my mother. I was born on a farm in the woods near my present home; but when I was four years old father was persuaded to abandon the farm, move into town, and work at his trade. He always had a longing for the farm, however; and after about eight years in the town (see p. 167, Feb. 15) he moved back to the old farm. It just now occurs to me that very likely he decided the farm would be a *better* place for his two boys approaching manhood. As we were about 2½ miles from church, one of his first moves was to get a six-seated carriage in order that he might take the whole family to "meeting" regularly every Sunday.

It happened, however, in this case, as in most others, that there were sabbath-breaking boys in the country as well as in the village, and my brother and I preferred rambling about with these new acquaintances rather than going to church. Father expostulated several times; but it seems we gave little heed, and, I am sorry to say, I cannot remember I had been to church with the family a single time until I was close to sixteen.

One Sunday morning, when my older brother and I were just ready to start off as usual, father came to us looking pretty stern. As well as I can remember he spoke something as follows:

"Boys, a responsibility rests on my shoulders. The carriage stands there ready to take you to church, and there is plenty of room. If you decide to go with us, well and good, and you are most heartily welcome to our home as long as you choose to stay. If, however, you choose to spend your Sundays as you have been doing, and with the crowd you have been going with, you will have to find a home elsewhere. I have thought the matter over for some time past, and I am sure I am right. Think it over, and take your choice."

As memory goes back, may God forgive me for being obliged to relate that, at that time, I regarded this as an encroachment on what might *now* be called "personal liberty." I advised that we go ahead as we had started, and suggested the "old gentleman" would probably "let up a little." Marshall, however, knew father rather better than I did, and suggested we "go to meeting" just this once, any way. I didn't seem inclined to agree, however, until he further added: "Ame, there is a lot of pretty girls up at the church, as well as off where we were intending to go," and that turned the scale. We went to church, and, singing in the choir of that country church, I caught about the first glimpse of her who is now Mrs. Root. Please don't smile, dear reader, when I confess that, after that Sunday, I needed no more urging toward *church-going*. My motive was not a very good one, perhaps, but it resulted in my hearing some good honest sermons that I very much needed at that age. It was the turning-point in my life. Father did not *say*, as did Joshua, "Choose ye this day whom ye will serve," but it came pretty near to it. It is, I happen to know, *just now*, a question as to how far a father shall go with boys just turning into manhood. To threaten to "turn the boys out of house and home" is certainly a pretty severe procedure; but what other course had he? Let me tell briefly how we had been spending our Sundays.

It is true we usually went to a Sunday-school in a country schoolhouse; but we went there only to interrupt the services and "have fun."* After Sunday-school we went to a sort of grocery (there were no *saloons* at that early day), and bought *beer*. One treated the crowd, and the next time another treated. As an evidence of my want of sense at that early age my brother had to inform me that after I had taken the beer others paid for it was incumbent on me to treat likewise. At that time my "income" was from chickens, and it came a little hard to take my well-earned "chicken money" to treat a crowd to *beer*. (Have any of our "chicken" readers had a like experience?) Well, I got the experience "good and hard." As the barkeeper filled the glasses he asked me if we would not like a little wine in with the beer. As it never

* Years afterward, when I started to serve the Lord one of my first promptings was in regard to that Abbeyville Sunday-school, and for eight years I went down there (five miles), winter and summer, and kept the school going. I have in past papers mentioned some of the results.

entered my head the spoonful of wine would cost any more I innocently said, "Yes, put it in;" but when he explained it was ten cents each instead of five, because of the wine, I became wiser and sadder also. I "wisely" concluded, also, even if I was only sixteen, that the "*chicken* business" would not *stand* any such "incidentals."

Had Eli "laid down the law" to his two sons Hophni and Phinehas, as my father laid down the law to *his* two sons, it *might* have averted that terrible war that cost Israel 34,000 men. The example these two set by profaning their holy office did at least very much to corrupt and lead astray the nation. It has been suggested more than once that the terrible war now going on in Europe is the result of letting men stand in high and sacred places who, like Eli's sons, "knew not the Lord."

Let us now go back and consider what might have happened to *me* had I chosen differently on that momentous Sunday morning. Like many another boy of sixteen I had not at that age any particular conscientious scruples about following my fancy for any particular "Delilah." In fact, I had already an eye on a girl I had met and talked with on those Sunday trips.

Just recently we had "Endeavor Sunday" here in Bradentown. The Endeavorers of all denominations had a *union* meeting, filling a great church. Our pastor gave us a splendid Endeavor sermon, and among other things called attention to the marriages that had resulted among the Endeavorers. He said the Christian homes they had established and were establishing were *model* homes, and were going to raise the standard of the nation. My friend, if you want a wife, look for her in the church or Sunday-school or Endeavor society.

Just a word about that expression in our last text, "that thy days may be long upon the land," etc. I am now over 75 years old, and able to do quite a lot of work besides writing these Home papers. Is there any probability that this would have been the case had I decided differently on that Sunday morning? Suppose I had kept on with the beer-drinking crowd, perhaps married the bold girl I had met (say at eighteen) instead of waiting until I was twenty-two, etc. Suppose I had cut loose from the dear old home and the praying mother—the mother who was doubtless praying for her boys *most earnestly* when they were settling the momentous question, "Choose ye this day whom ye will serve."

BEE "KEEPING" BY A. I. ROOT; "THAT BEE DISEASE."

Since A. I. Root has become "really and truly" a *beekeeper*, you would naturally expect some words of wisdom from him on the subject. Well, I think they are coming. Before the "wisdom," however, I want to say that it seems that, wherever I go, people *will* introduce me as "the great authority on bees;" and one of the papers recently was so kind as to say I probably knew as much about bees as "any man living," etc. Of course, I try to explain (modestly, of course) that I *was* "pretty well up" in a former age; but "the present generation," etc. Now for the wisdom.

About a week ago I noticed some immature bees and larvae out on the ground in front of that three-story hive; but as the bees seemed very busy on the advance orange bloom I supposed they must be putting some honey above; for when last examined they had quite a few sealed stores; but the morning after finding a teacupful of dead bees were out in front, and more that could just crawl on the bottom-board, I tell you that hive was pulled apart quick.

There wasn't a cell of honey in the whole colony, and scarcely a cell of unsealed brood, although there was a *big lot* of sealed brood in almost every comb below. With the cold rains we are having (three times the normal amount of rain during the last winter), they had been able to work only "from hand to mouth," with the great amount of brood they had been caring for. I got a jar of honey "in a jiffy," and, holding it high up, let it drizzle slowly into the empty cells. The honey was *really* about half hot water, so they could handle it quickly; and after the hive was closed up you ought to have seen the rejoicing. They poured out of the hive almost as if they were going to swarm, and then danced in the sunshine to express their thanks for their sudden and unexpected timely deliverance. It made me think of some of my timely answers to prayer, when I was caught unexpectedly in sore straits. To make sure of no more such "blundering" I gave them a whole pint of honey next day, poured into the empty combs in the upper stories. How is the above for the "great beeman" with only *one* colony of bees to care for? I then put the dead bees on the ground in front, in a corn-popper, sprinkled them with sweetened water, then placed them in a warm oven, after the fire was all out, but only a few revived. They had been neglected just a little too long. Of course they are all right now, but my loss through almost criminal neglect is all

the unsealed larvæ right in the middle of March, during orange bloom.

The above reminds me of an incident of perhaps thirty years ago. A prominent judge came to me one morning during fruit bloom, saying his bees seemed to be "sick," for they were crawling about listlessly in front of the hive, instead of working on the apple bloom, etc.

He said, "Mr. Root, I reasoned that, if there was any disease that afflicts bees, you would be the man of all others to diagnose it, and you would also be more likely to know the specific remedy, if there was one." As soon as I lifted his hive I replied:

"My good sir, I am glad to tell you I do know all about the trouble, and the proper medicine, and that I can cure your bees in a few minutes. Get me a teacupful of sugar and some hot water." I sprinkled the warm sugar and water on top of the combs, and also a little on the almost lifeless bees in front of the hive, and in a few minutes there was a glad uproar. The learned judge said he never before heard of sugar as a *medicine*.

Again, when Mrs. Root and I were in California, one morning a young man with a fine span of horses and buggy drove up to our boarding-place. He said I must go out in the country and look at his bees, for he was in trouble. He insisted that Mrs. Root should go also; but when we got there his good mother was in a flurry because he had not told her he was going to bring home company to dinner.

I am going to have two morals to this story, and one of the two is this: Don't ever bring company to dinner without first informing your wife or mother that you wish to do so.

In spite of Mrs. Root's protest the good woman *would* work hard to get up "a fine spread."

Well, I found fully 50 colonies of bees, more or less, afflicted with the "disease" (?) we are talking about. Some were too badly "affected" to be fully restored; but with a pailful of sugar and a teakettleful of hot water we soon had the whole outfit filling the air, and rejoicing in health, and the owner and his mother both happy and wanting to pay us for just telling them the bees were simply *all starving*.

Once more, when your hives are full of brood, especially unsealed brood, it takes a pile of honey and pollen to fill the hungry mouths. Right in the midst of a honey-flow, or what should be a honey-flow, I have often found populous colonies without a cell of honey in the whole hive *in the morning*, when the combs seemed, the night be-

fore, to be fairly supplied. Now, if cold rainy weather comes on, say for a day or two, the honey crop is often curtailed to a greater or less extent, and yet the owner may never know nor even *guess* what caused his disappointment. Just a temporary check on brood-rearing at a critical time results in less. This is my *second* moral, and if it shall cause *you* to be more watchful I will try to think *my* blunder was providential, inasmuch as it caused me to give you this warning.

"WATER-WITCHING," ETC.

I wish to write a few words on the subject of water-witching, in which you have often expressed disbelief. I never believed it, and can't say that I do yet, but wish to tell you of what happened in this neighborhood, where water was apparently found by this method on a farm two miles from here. The farm was owned by two young men who, however, did not live on it, but kept it for pasture. There were two wells on the place, but they always went dry when there came a dry time. The summer and fall of 1913 were exceptionally dry in Ontario, and I believe it was so in many parts of the United States. In the early part of August these two wells went dry, and it was very inconvenient, especially as the owners did not live on the place. Their brother's hired man, who lived five miles away, heard of this, and said he would find them a well by witching providing there was any water on the place. He came over one day and "located" a well 20 or 25 rods from the other wells. He said they would have to go down 30 or 35 feet; or if they got water any sooner it would be a very strong spring. As soon as they got their harvest off toward the beginning of September they started to dig. I often talked with them, and laughed for trying to get water by this means. At 23 or 24 feet they struck a very strong spring which rose to within nine feet of the top ground. The well is as good as ever to-day, and *seems* to prove something in favor of water-witching.

Brucefield, Ont., Can. HUGH MCGREGOR.

My good friend, in the above case two wells were dug (you don't tell the depth), and no permanent water; but a third one, a little distance away, gave a good continuous supply. This often happens, as we all know.

Let me repeat: God and nature are "no respecter of persons." Every *real discovery* in the realm of science works alike with *everybody*. In all the reports that have come to me, I have never yet found an educated scientific man (say like our college professors) who could locate wells as above. It is conceded by all that the subject will not *bear* the searchlight scrutiny of up-to-date science. It won't even "work" when the operator is blindfolded.

Possibly you may be interested in knowing that I had a colony of leather-colored Italians (propagated from nuclei bought of you) in a ten-frame sectional hive that produced 70 shallow frames of comb honey last season—just a little over 280 lbs. of surplus honey. The queen was one year old last July. All my bees did well, a few colonies averaging considerably over 100 lbs.

Lynchburg, Va., Dec. 2.

A. P. ROBERTS.

HIGH-PRESSURE GARDENING

OUR FLORIDA GARDEN, ETC.

A few days ago a representative of our Bradentown *Evening Daily* paid us a visit. He pretty soon took out his notebook and pencil and tried to take down the names of some of the new plants from the Department of Agriculture; but when he came to *Jabotica caba*, *feijoa*, etc., he gave it up. I have left out some, and made slight modifications where he did not quite catch my hurried talk.

"NEVERSWAT" FARMER BUILDS SCAFFOLD TO SUPPORT FINE FRUIT.

A. I. ROOT MAKES PILLOWS FOR PAPAYA "APPLES" LARGE AS WATERMELONS TO REST UPON; COLLECTS DASHEENS FROM MANY LANDS; MAN WHO KNOWS ALL ABOUT BEES TAKES DELIGHT IN TESTING POSSIBILITIES OF FLORIDA SOIL AND CLIMATE, AND IN PROPAGATION OF FANCY AND USEFUL NOVELTIES.

A. I. Root who maintains a winter home on Richland Avenue, who knows more about bees than any other person in this "neck of the woods" (and probably more than any one else in the world), is the champion never-sweat farmer in this part of the earth. Indeed, the man of large affairs, who delights in spending his winters in Florida, is so enthusiastic in the matter of his farming operations that he can scarcely take time from his wonderfully interesting garden to make the trip to the postoffice or to the corner grocery with dasheens and duck eggs with which to pay the family grocery bill.

"About forty years ago," Mr. Root said at the home yesterday, "I became interested in the study of bees. Some folks said that I was mad on the subject of bees," he remarked with a smile, in remembering and relating the conditions of so many years ago; "but when I discovered and demonstrated that I could take a barrel of honey in a season from a single colony of bees my critics were forced to admit that at least there was method in my madness."

It would be a difficult matter to find one in any station of life who is apparently happier in his work than is Mr. Root in his. In the beautiful garden which is a part of the splendid homestead in the southwest part of the city the owner takes special delight in collecting rare and possibly promising specimens of fruit and vegetables from all over the world, and it is frequently his pleasure to enjoy the juicy freshness of some new variety that cost him several dollars a pound. He enjoys this novel experience with the same relish that he does the dasheens which he takes from hills producing half a bushel to the plant. It is all the same to him. He is a philanthropist in his work to the extent of seeking to propagate varieties of fruit and vegetables which will prove valuable for general cultivation in addition to the varieties which he cultivates purely as novelties.

In his collection of dasheens there are varieties from South Africa, from South America, and other tropical lands. He sees in these a valuable crop whose cultivation and uses should be more generally understood and appreciated. Every part of the plant is edible—not only edible but exceedingly desirable as a food, Mr. Root says. The tubers are better than potatoes, he believes, as a food, and he likes them, baked, twice a day. The stalks are fine and tender, and pleasant to the taste as asparagus, a real luxury of the North, and the leaves are equal in desirability to the best of spinach greens.

Mr. Root's specimens of the dasheens from South

Africa and South America are gifts from missionaries who were his friends, and are prized because of their associations.

In the wonderful garden which constitutes a revelation to the northern visitor who is unfamiliar with the marvelous possibilities of Florida soil, a specimen of the *Papaya carissima* flourishes. Missourians call it pawpaw, although the pawpaw of the Missouri bottoms is quite different from the fruit in Mr. Root's garden. The odd and even unusual thing about Mr. Root's papaya-tree is that he has scaffolding constructed all about its body like the scaffolding about a house in course of construction.

This work does not constitute a device for saving the tree, but is a support for the fruit, of which there are eight or ten specimens, some of which are beginning to ripen. They are so large that it is necessary to build the support about the tree to hold crossbeams upon which the fruit rests, on padded cushions.

Mr. Root is cultivating a large number of trees which are rare and almost unknown in America, whose names can be spelled only through the diligent aid of the most classical works on botany. He has rainbow corn, one of Burbank's novelties, and specimens of his spineless cactus, growing close to the old-fashioned peas and beans like those which grew in grandma's garden, and the Irish potatoes, the real thing in "Murphies," in which the winter resident rejoices.

While Mr. Root enjoys working with his own hands in the development of his Florida property he keeps a man who devotes his time to the care of the premises and the cultivation of the various crops produced there, including a splendid yard of chickens and pens of Indian Runner ducks. He has invented his own arrangement for baffling the efforts of the woods rats to rob his poultry. A galvanized tub set on the stump of a tree provides a unique feeding-trough for the chickens, and a tub planted in the soil and filled with water, in which grain is cast, furnishes an ideal feeding-trough for the ducks, and is rat-proof.

While the matter of profit is not a consideration with the farmer who loves to revel in the splendors of the Florida winter, it nevertheless is a source of satisfaction to him to know his products, many of them, even when grown in an experimental way, are produced at a profit.

Mr. Root likes Florida so well that he would like to remain here the year round; but Mrs. Root remembers five sons and daughters, all married and living in separate homes, and within talking distance of the old homestead in Medina, Ohio, which is their home town.

There is a bevy of grandchildren, also living in the homes about the old homestead; and soon after the annual migration of the wild birds she insists on moving back where she can be near her treasures.

HELIANTI, THE NEW FLOWERING PLANT AND VEGETABLE, ETC.

Last May one of our readers sent me a circular in regard to this plant, and in our issue for May 15 I severely criticised the Burgess Seed Co., who sent out the "glowing" circulars; but in the June issue I gave notice that the above seed company procured the seed and circulars from a prominent seedsman. The Burgess Co. also kindly sent me a few tubers for trial. In

our Oct. 1st and Nov. 15th issues I made a report. Well, I brought tubers, and also *seed*, down here in Florida, but so far have entirely failed to get either to germinate. This failure may be owing to the very unusual amount of cold rains we have had. These little tubers are certainly a very delicious vegetable; but so far the yield at our Ohio home is not any thing near what is advertised. Although the plants were away above my head, and covered with very pretty little "sunflowers," I don't think I got a pint of tubers to the hill, and it was a lot of trouble to get them out of our clay soil, as they are seldom as large as your little finger. As they are surely a nutritious and delicious vegetable I really hope that, in some soils, they *may* go up to "2 or 3 hun-

dred bushels per acre." In our Nov. 15th issue I did not give the Burgess Seed Co. proper credit, because I was told by somebody they were out of business; but I since learn they had only moved their seedstore from Allegan to Galesburg, Mich., where their seed-farm is located. They now send out a very pretty little catalog describing helianti, the winter melon, guada bean, etc. The catalog informs me that the reason we did not appreciate the guada bean was that we attempted to cook the *mature fruit*, whereas it is only the small young ones that are "equal to asparagus," etc. As I now take it, you might as well undertake to eat a "ripe cucumber." The Burgess folks *guarantee* their seeds—no such talk as "after this our responsibility ceases," etc.

TEMPERANCE

"WHAT DO YOU THINK?"

My dear Brother A. I. Root:—In the last half of the second column on page 875, November 1, I find some questions asked for your friends to answer. As I consider myself one of your friends, allow me a word or two in your temperance department. You ask, "What do you think of the man who made money by selling the whisky that caused the poor crazy man to fight with, and *kill*, his poor innocent hard-working *blind* wife who was *tied up* to a drunken husband?" Allow me to ask a question in answer: Would any of the readers of GLEANINGS think the whisky-seller should work for the United States Government for just a bare living? Do not all Government employees get better pay than that? It is *well* that we do not forget that the *saloon-keeper* is a necessity in the economy of these United States if we are to have "half our government expenses" paid. See first column of GLEANINGS for September 15, 1913, page 663. I should prefer that the half of my government expenses be paid by a direct tax; but so far I have been unable to have my say in this matter.

Next you ask: "Can any church-member, in the face of the above, think for a moment of voting wet?" No, I cannot. But, dear reader, what is voting wet? I charge, without fear of successful contradiction, that nine-tenths of the voters of the United States did vote "wet" on November 3, 1914; otherwise all the congressmen who stood pledged that this liquor-taxed, licensed-saloon business for revenue should continue, if they were elected, could not have taken a seat at the head of our government. And how many of these were elected by the *sovereign* voters of the United States? All but one. One congressional district in California said their congressman should carry his part of this government "dry." And if all the other congressional-district voters could have done their "church-member duties" in the same way this country would have been as dry after the 4th of next March as in Russia today; and this people had the proof that the only way to kill this cursed business was to "knock it in the head." See GLEANINGS for July 1, 1914, page 526. It took an Old World monarch to teach us how this nearly one-sixth of the area of this world of ours could be made "dry" in one day—yes, absolutely dry. Shall we heed the lesson? In your familiar call, "May God help."

Borodino, N. Y.

G. M. DOOLITTLE.

PROHIBITION IN KANSAS; BY CONGRESSMAN

JOHN CONNELLY

When I read the *American Issue* I am tempted to clip for GLEANINGS from almost every article. I wish our *Ohio* readers at least would subscribe and read it all.

To-day we issue a challenge, and feel free in so doing. We dare you to find a community in Kansas where the abolishing of the sale and manufacture of liquor has permanently increased the taxes raised in other ways; where it has increased the crime in the community or contention among its citizens; where it has increased want and misery among her people, or has made it more difficult for men to reap a recompense for their honest endeavor. I know little about the workings of prohibition elsewhere; but when those who are opposed to the principle desire to point out a place where prohibition has been a failure they must leave Kansas out of their calculations.

I am glad to speak to-day for the splendid commonwealth of prohibition Kansas. Half a million boys and girls tread her highways who never saw a place where liquor was legally sold, and a hundred thousand of them never saw a drunken man, nor do they know the taste of liquor. The older generations are not entirely free from the baneful effects of the liquor habit; but from the loins of that mighty people there is coming into maturity the new generation free from the tyranny of its hurtful reign. May it please God that, with the coming of another generation, we may not only appreciate the benign influence of statewide prohibition, but may we hope there will soon be no place where a licensed grogshop may find lodgment under the protecting folds of the national flag. For this we dare to hope, for this we dare to pray, for this we dare to vote.

"BY THEIR FRUITS YE SHALL KNOW THEM."

We take pleasure in submitting the following from the *Sunday School Times*:

A few weeks ago a Philadelphia man and his wife decided to give up drinking. When the regular case of beer was delivered to the house the woman reported that she asked the driver to remove all of the empty bottles that were in the cellar. "Now you

may take away that full case of beer, and not bring any more here."

"Would you mind telling me," said the liquor man, "whether Billy Sunday had any thing to do with this?"

"Yes, he did," answered the woman; "we've been to the meetings, and decided not to drink any more."

"You are the tenth customer," he said, as he prepared to depart; "you are the tenth customer that I have lost to-day on account of Billy Sunday."

And that was two weeks before the Booze sermon was delivered!

"GOD'S KINGDOM" COMING.

And the following also, from the same issue:

The claim that more liquor is being consumed to-day than ever before is one of the claims that trouble many temperance people. Billy Sunday brought this claim into the open and met it with a printed report that was given to him by a government official. The figures given were by the United States government. The whole tabernacle smiled with Billy as he told them confidentially that he had friends on the inside who kept him posted on the real facts. He chuckled with pleasure as he held the sheet in his hand; and as the laughter quieted down he hurled these figures at the audience. For the government year ending 1914 the amount of whisky that was consumed in the United States was 10,741,738 gallons less than was consumed in the year ending June, 1913!

OVER 189 MILLION PASSENGERS CARRIED, AND NOT ONE KILLED.

SAFETY FOLLOWS SOBRIETY.

In 1914 the Pennsylvania Railroad Company throughout its entire system carried 189,167,326 passengers, and not one of these passengers was killed. This is the company's star record. It will be remembered that the Pennsylvania company strictly enforced its rule against drinking on the part of its employees, does not sell liquor on its dining-cars, and has closed the bars in all of its stations.—*American Issue.*

"CAPT. RAND" AND HIS "LUCKY STONE."

Dear Mr. Root:—Please print in GLEANINGS your opinion of the so-called "lucky stone."

Surrey, Cal., Nov. 17.

MRS. ANNA ROSE.

My good friend, the above has been referred to two or more times already. It is, of course, useless to pay out a dollar for a common pebble so as to insure the owner "good luck." A horseshoe nailed over the door will do the trick just as well, for we all have more or less good luck every day of our lives; but we never take note of it (nor thank God for it) until we have invested our dollar in an innocent pebble.

ONE CIGARETTE, AND WHAT IT DID.

We clip the following from the *Christian Herald*:

ONE CIGARETTE, \$500,000.

Starting, it is alleged, from a cigarette thrown into some rubbish, a fire destroyed railroad property at Camden, N. J., January 8, to the value of more

than \$500,000. The railroad station and ferry slips of the Atlantic City Railroad Company and some twenty-five vestibule cars, besides a nearby lumberyard, were destroyed; a dozen persons were seriously hurt, and over one hundred firemen were overcome by the smoke. It required the services of eighteen local fire companies aided by apparatus and fire-boats from Philadelphia to subdue the flames, which were fanned by a north wind. Thousands of spectators watched the spectacle.

One addicted to the cigarette habit, as a rule has too little sense to know any better than to throw the burning paper into any combustible matter.

WOULD WOMEN VOTE IF THEY COULD?

In answer to the above we clip the following from the *Woman's Journal and Suffrage News*:

At the presidential election in Arizona in November, 1912, when women could not vote, the total vote cast was 23,722. At the gubernatorial election in November, 1914, when women did vote, the total vote cast was 51,007.

In like manner in Kansas, in 1912, the presidential vote was 365,444. In 1914 the gubernatorial vote was 530,206.

Oregon, in 1912, cast 137,404 votes. In 1914 it cast 210,566 votes.

At the gubernatorial election of 1910 in California the last general election at which men alone voted, the vote was 385,713. In 1914, at the gubernatorial election, with women voting, it was 926,689.

In Washington, at the 1908 election, the vote for governor was 176,141. Women were enfranchised in 1911, and the vote in November, 1914, was 345,279.

These are the latest five States in which women have had an opportunity to vote at a general election. The difference between the vote before and after equal suffrage should put an end to all arguments that women do not use the vote.

"THE FATHERHOOD OF GOD AND THE BROTHERHOOD OF MAN."

My dear Mr. Root:—I am inclosing \$1.00 for the renewal of my subscription. I am not handling bees, but in a general way I am interested in the discussions and experiments on that line. The honeybee has been one of the potent agencies in our American civilization. The same may be said of our horticultural productions. Furnish the home with fruits and honey, and the home is far more complete and happy. Our heavenly Father has provided a supply for the legitimate wants of every living creature; and with a proper adjustment in our social relations every need of every human being can be supplied, so that there should be no necessity for war.

Our Father is rich in houses and lands,
Rubies and diamonds, silver and gold,
He has riches untold.

But the wastes from war and dissipation to the present time would build for every family on earth a palace of marble and decorate it with gold, so that Aladdin's dream might be realized.

I am interested in your apology; but for me the greater attraction is in the common-sense sermons which you are preaching to what is one of the largest congregations in the world. The world is learning that true religion does not consist in mere profession, ceremony, or ritualism, but a life and character which is in harmony with the spirit of Christ—a religion which recognizes the fatherhood of God and the brotherhood of man.

Bees in Apple Orchard

The Lure of the Land, \$1.50

By Harvey W. Wiley, formerly Chief Chemist of the
United States Department of Agriculture

Gleanings in Bee Culture (1 Year) \$1.00

Both for \$2.00 Postpaid

The author of **THE LURE OF THE LAND** encourages business men to gratify their longing for the freedom of the open air, but at the same time portrays the problems to be solved and the hard work required in order to make farming pay. A very readable book, human in quality, yet invaluable for reliable information. See what A. I. Root has to say about it on advertising page 18, March 15th issue.

Range of Topics Included in **THE LURE OF THE LAND**

The Lure of the Land,
The Boomers and the Boomees,
The Born-on-the-Farm Myth,
The Dairy the Hope of the Small Farm,
Health on the Farm,
Farm Labor,
Prohibition for the Farmer,
Is the Small Farmer to Disappear?
The Place of the Farmer in the Social Scale,
The Farmer's Market,
The Farmer and Parcel Post,
Farm Finance,
Back to the Farm,
Genesis of the Soil and Its Possibilities,
Power on the Farm,
What Is Becoming of Our Soils?
Dry Farming,
The Function of Water in Agriculture,
The Decreasing Meat Supply,
Uncle Sam's Big College,
Uncle Sam's Big Farm.

Renew your subscription to **GLEANINGS** in connection with
an order for a copy of **THE LURE OF THE LAND**.

Both for \$2.00

Canadian postage, 30 cts. extra; Foreign postage, 60 cts. extra.

NO. 8

EDITORIALS

Our Dismal Swamp Apiaries

SINCE our last report, page 258, conditions at our Dismal Swamp apiaries have improved materially. The bad weather did not hurt us after all. Indeed, we begin to feel that we shall secure nearly the increase we set out to make in the first place. Our Mr. Pritchard reports that the bees are booming. More anon.

Wintering in Medina

INDICATIONS in Ohio show that the winter is not going to be as serious as we once feared it might be. The loss will be somewhere about 30 per cent, and that mainly in the colonies that had aster stores from the swamp. The bees, however, in big quadruple winter cases, no matter what the stores were, seem to be coming through in excellent condition.

Wintering over the United States

So far it has been a late, chilly, cold spring in the South as well as in the North. In many localities the season is estimated at from three weeks to a month late. There is danger that there may be some heavy winter losses of bees this year. If the cold spring continues, spring dwindling will doubtless get in its work. Please send in postal-card reports of how bees are wintering, and we will publish a summary in our next issue.

Later.—Weather has moderated all over the country. It is to be hoped that we may have good weather from now on.

A Strain of Caucasians that do Not Run to Swarming

MR. HERMAN RAUCHFUSS, of Denver, Colorado, has a strain of Caucasian bees which he secured in the Caucasus ranges some years ago, and which, he says, are fine workers, very gentle, and do not run to swarming like those we had. He is not in

the queen business, but has been keeping this strain from year to year because they have been doing remarkably good work for him in honey production. They breed up early, and will go to the fields earlier and later than the ordinary Italian strains.

Back Home Again

E. R. Root has finished his western trip. Since being away he has covered over ten thousand miles, going from the eastern coast to the western coast, with stops here and there. It has been a whirlwind of a trip. Except for two or three days at the Dismal Swamp, Virginia, ten days at home, two days at Salem, Idaho, four or five in San Francisco, two days in San Diego, Cal., he has not slept twice in the same bed nor even eaten two meals at the same place. There are many of our friends whom he had to miss seeing, particularly in and about San Francisco, Los Angeles, and San Diego.

For a few weeks the editorial department will have something of a western flavor. Indeed, it began to take on that complexion in our issue for March 1.

"One of the Boys"

WE had a most delightful interview with P. C. Chadwick, in his California home. In this issue, page 309, he refers to his "boss," as he calls him, as "such a warm, open-hearted man! just one of the boys." We appreciate the compliment. To be one of the "boys" and nothing more is enough. Incidentally we might remark that Mr. Chadwick is another one of the "boys" whose home life is delightful. He has a family of which any man may be proud.

He is one of Uncle Sam's mail-carriers; but he is operating two outyards of bees, and one of the prettiest gardens that one can find in the United States. A. I. Root, if he could see that garden, would be one of the "boys" for a little while, sure. He would say "My stars!" at every turn. We

congratulate ourselves more than ever that we have an all-round man like our correspondent to represent GLEANINGS on the Coast. He knows the horticultural as well as the apicultural proposition.

Denatured Sugar

AT one of the last sessions of the National Beekeepers' Association, Dr. Jager, the man in charge of the agricultural school at Minneapolis, suggested the matter of using denatured sugar. In Australia, for example, the beekeepers petitioned the general government to remove the duty from sugar fed to bees; but in order to prevent such sugar from being used by the public generally, a scheme was employed to "denaturize" the sugar, or, rather, to color it so it could not be used for domestic purposes. An infinitesimal amount of coloring matter which could in no wise be injurious to bees colors the sugar just enough so it can be used only for bees. In this way it is made available to the beekeepers at reduced prices without the duty.

Dr. Jager suggested that the National Beekeepers' Association pass a resolution asking the general government to make some provision by which the beekeepers of America could use a similar denatured sugar. The question was debated for some time, when it was finally decided to hold the matter for future consideration.

Educating the British Columbians

WHAT is a skilled beekeeper? F. Dundas Todd, foul-brood inspector for British Columbia, says the difference between skilled and unskilled is that the former secures a crop three times as great as the latter. In his circular on honey production in British Columbia for the season of 1913-14, he shows that there are also about three times as many unskilled beekeepers as skilled, as we might expect. The average crop per colony reported by the skilled class was 84 pounds in 1914. Were all the amateurs shortly to become as experienced as the skilled beekeepers the local market would be swamped unless the honey were disposed of elsewhere.

The people of the province are rather poor consumers of honey, so there is plenty of room for development of the market. The buying public must be tempted by attractive packages and attractive advertising. British Columbia has all the qualities one could desire in honey. The main thing is to prove this.

The Three-cornered Alfalfa Hopper

THE importance of alfalfa as a honey-plant makes of interest to beekeepers any information regarding its pests. Perhaps the most difficult of these to eradicate, as well as one of the most active, is the "three-cornered alfalfa hopper" (*Membracis festina*), the subject of a recent monograph by V. L. Wildermuth, published in the Jan. 15th number of the *Journal of Agricultural Research*, Washington.

Alfalfa is not its only food. The insects have been found on a great variety of plants, particularly on clovers. Of alfalfa, however, it seems to be particularly fond. Injury is due to the sucking of plant juices by both adults and larvæ, and the development of a feeding ring or scar. The insect leaves the plant in a wilted and often dying condition.

While no method has yet been discovered which will entirely control the pest, its numbers may be greatly reduced by clean methods of farming, such as the eradication of weeds, rubbish, etc.

While the alfalfa hopper is found in greatest abundance in the southwestern and southern part of the United States, it extends its range in limited numbers as far west as Montana and as far north as Ottawa, Canada.

Adulterated Beeswax

THOSE who are buying beeswax in any quantity are cautioned to look out for adulterated beeswax offered by dealers at a cent or two below general market price. It has been found that some of these cheaper waxes contain from 5 to 10 per cent of paraffin or ceresin. Those who have put out this adulterated product have probably been laboring under the assumption that wax containing so small a percentage of adulteration would not be suspected, and therefore not put to the chemical test. Ordinarily the "crack" test to an experienced eye will show as low as five or ten per cent, providing, however, that such an experienced eye is on the lookout for these low percentages of adulteration.

Again, it has been generally supposed that ordinary beeswax in cakes of all sizes and colors is probably pure, the presumption being that such wax is gathered up from numerous beekeepers, who, of course, use all kinds of utensils to *cake* the product; but some of the adulterators have learned this trick, and have been buying up old pots and kettles, even going so far as to dent or jam some of these pans slightly out of shape.

Grasshopper Enemies of Alfalfa

WHAT insects attack alfalfa are of concern to the producers of alfalfa honey, in some indirect measure at least, since prosperity depends upon their control. Two or three common species of grasshopper, their habits, and the methods of preventing or destroying them, form the subject matter of Farmers' Bulletin No. 637, "The Grasshopper Problem and Alfalfa Culture." This new circular will be of interest wherever alfalfa is threatened by an attack of these insects.

One of the enemies is known as the differential grasshopper, another as the two-striped grasshopper, and the third *Melanoplus atlantis*. Others have been reported to have had a part in the damage, but these are the principal culprits. Since the eggs are laid just below the surface of the ground, the most effective means of preventing their hatching is to plow or dig the soil to the depth of two inches. Full-grown insects may be destroyed by the use of a hopperdozer, a simple coal-oil pan dragged over the ground, or by means of poisonous bait.

Unless steps are taken to eradicate this pest, it is possible it may assume serious proportions.

Not Winter Nest but Aster Stores Responsible for the Loss

OUR friend and correspondent Mr. J. L. Byer, of Canada, in our issue for April 1, in his department, says: "It is not often that the editor gives me such an opening as that on page 176, March 1, when he tells of so many colonies being dead." Then he goes on to give it as his opinion that the death-loss was due to "too much winter nest." Perhaps we should have explained on page 176, which we did not do at the time, that the bees referred to consisted of ten colonies in double-walled packed hives by themselves in the Blakeslee yard, and an equal number at the Harrington yard. These colonies had come from the swamps near Akron, and were supplied almost entirely with aster stores. As a matter of fact, they did not have a winter nest, but had solid stores of aster, or practically aster honey, and, furthermore, they were not very strong to begin with, but were no weaker than those in Holtermann quadruple winter cases. While there was a 30 per cent loss, there was only one dead out of sixty in the Holtermann winter packing-cases having the same stores and about the same strength per colony.

We did not then realize the fact that aster stores were going to prove so troublesome; but later events showed this very clearly. The incident, so far from showing that the winter nest is a bad thing, proves nothing on that point, but, rather, goes to show that the death-loss was due to the quality of stores and an insufficient packing for the kind of stores. It also showed that combs of solid stores did not save them.

Prof. Gillette on the Trouble in Western Colorado

WE had an interview with Professor C. P. Gillette, Entomologist at the Experimental Station, Fort Collins, Colorado. We referred to the fact that statements had been made that large numbers of beekeepers had lost heavily on account of the spraying liquids falling on the cover crops under the fruit-trees on the western slope of Colorado. He admitted that this was probably true, and was urging the fruit-growers to plow these crops under, or to cut them before they go into bloom. No trouble, he said, arises from the sprays that fall on the fruit-trees, because the fruit-growers for their own protection, and because there is a law against it, do not spray while the trees are in bloom; but red clover, which is chiefly used as a cover crop, comes into bloom when there is a general dearth of honey, and at the very time when the trees are being sprayed with arsenate-of-lead solutions.

Prof. C. P. Gillette is a friend of both the fruit-grower and the beekeeper, and we may rest assured that he will do every thing that lies in his power to prevent the further destruction of bees.

Making All the Clover Seed Germinate

ONE of the discouraging things in clover-raising has been the low germination of the seed, due to the hardness of the seed coat. Only a small proportion of the seed of the common clovers can be expected to produce plants. Now the Iowa Experiment Station announces that it has constructed a practical machine by which it is possible to scarify the seed coats and thereby increase the germination of legume seeds to over 90 per cent.

The first machine with this efficiency was constructed in December, 1913. No announcement was made at that time, however, in order to allow time for field tests comparing treated and untreated seed, in

addition to extensive germination tests. A large number of plots were seeded on the station field in the summer of 1914, comparing treated and untreated sweet-clover seed from various sources. In a large number of cases, stands which were, if any thing, too thick, were secured from the treated seed, when the same seed seeded at the same rate and time, but not treated, failed to produce any stand at all. The machine as constructed has a capacity of approximately 25 bushels per hour, and requires about four-horse power to operate it. It is estimated that it can be put on the market at a price not to exceed \$90 to \$100.

The construction of the machine represents eight years' work on the part of H. D. Hughes, Chief in Farm Crops.

During the spring of 1914 and 1915 several thousands pounds of sweet-clover seed were treated for individual farmers. A farmer for whom the section treated some 3000 pounds of seed in the spring of 1914 states that the seed germinated approximately 50 per cent when sent to Ames, but germinated 98 per cent when returned. Another reports using 5 pounds per acre of treated seed, from which he secured a perfect stand, while the usual rate of seeding ranges from 15 to 20 pounds per acre with many failures and uncertain stands resulting from poor germination.

While it is too early to predict the indirect effects of this invention on beekeeping, it may ultimately be of great value. Any thing that will increase the number of honey-plants in an acre of ground will make it more easy for the bees to gather nectar, especially in lean years. An invention that will treble the effectiveness of all the clover seed is likely to mean much to those who depend so directly upon the clovers as the beekeepers do.

Dr. A. J. Cook, Horticultural Commissioner of California

IN our last issue we referred to our interview with Dr. Cook. We had the pleasure of meeting him for an hour between trains, and he is the same old Professor Cook whom we used to know away back in Lansing, Michigan. He was always an original investigator and a lover of bees, and interested in all lines of horticultural work. As Entomologist at the Michigan Agricultural College, back in the early days, he did some invaluable research work. Among other things, he was among the very first, if not the very first, to make some direct experiments in testing out the value of bees as

pollenizers of fruit-trees. He covered the limbs of certain trees with mosquito-netting before they came into bloom. The result of all this work showed how necessary was the work of the bees. Similar experiments were made by others at a later time with the same results.

Dr. Cook was probably the first to suggest the use of oil emulsions for the destruction of the San Jose scale. About the same time Dr. Riley, then Chief of the Bureau of Entomology, Washington, D. C., was conducting similar experiments and claimed the honor of the discovery; but Cook, we think, from the evidence in hand, was a little in the lead.

Cook was also the first to show that honey is a predigested sweet, or, as he called it at the time, "digested nectar." He was ridiculed by many at the time, even by prominent beekeepers, for putting out such a "heresy;" but now the whole scientific world acknowledges that honey, before it comes to the human stomach, has already gone through one stage of digestion.

Dr. Cook, notwithstanding he is well advanced in years, seems to be in the very prime of his youthfulness. His aggressive pioneer work has sometimes made him enemies; but all he asks is that his work be thoroughly investigated. At times the attacks that have been made on him have been particularly bitter. False charges have been hurled at him; but to-day he stands vindicated as one of the strong men in his state.

The Editor of Gleanings Interviews the Editor of the Western Honey Bee

WE had the pleasure of visiting Mr. J. D. Bixby, the genial editor of the *Western Honey Bee*, at his home in Covina, near Los Angeles, Cal. He is one of that kind of men who wear a smile that never comes off. In fact, we had a most delightful talk with him concerning problems connected with the beekeeping industry in the East as well as in the West. In this connection it should be noticed that Mr. Bixby originally hailed from New York, where he had a considerable experience as a beekeeper. He has continued his bee operations in the West for several years back so that in a sense he unites the East and the West. He is eminently well qualified to take up the editorial management of a bee-journal; and, so far as we could learn, that paper is making good on the Coast.

Mr. Bixby is one of that kind of bee editors who are almost every day among

their bees. When we met him he had on his overalls, for he had just come from his shop where he was preparing some supers.

Mr. Hutchinson, the greatest bee editor this country has ever had, once remarked to us that the man, other things being equal, who wrote an article on a hive-cover with a pencil daubed with bee-glue usually wrote something that smacked of experience. Mr. Bixby is evidently one who draws inspiration direct from his bees; if so, all the better for the *Western Honey Bee*.

In speaking of the orange country for beekeeping, Mr. Bixby made this significant remark: The citrus region makes a good *bee* country, but not an extra-good *honey* country. In other words, the orange-groves will furnish honey fast enough to build up colonies amazingly, and one can raise bees very easily; but it is not so easy to get the honey. The only way to accomplish this is to make all colonies strong. The brood of all the weak colonies is given to the fair ones, so there will be nothing in the yard except strong ones. With these one can get a crop of orange honey if the season is any way fair. Where orange is followed by sage or some other stores, one has a good honey country. But it is not often that one can have this combination.

Government Honey Cook-book

VARIOUS ways in which the housewife can use honey to advantage are suggested in a new publication of the United States Department of Agriculture, Farmers' Bulletin No. 653, "Honey and its Uses in the Home." This bulletin is now ready for distribution, and can be secured free of charge by dropping a line to the Department.

Every beekeeper or any one else interested in the use or sale of honey should secure a copy of this bulletin at once. It is crammed with suggestions for the broader use of honey as a substitute for high-priced sugar, and with recipes for delicious cakes, cookies, and other dainties. Many of the recipes have already been published in this and other magazines, and the suggestions have been gathered from many sources, but at the same time the Department has been making experiments which showed that many of the old recipes are unnecessarily elaborate.

Any suspicion that the public may have regarding the adulteration of honey is dealt a hard blow by the statements, "There is now, it is believed, little adulterated extracted honey on the market," and "Comb honey is practically certain to be the pure

product of the hive, because it can be adulterated only by processes which cost more than they save."

Wholesale attention was called to this bulletin, and much of the valuable matter in it was brought out, by a press notice of the Department, which was sent to every newspaper in the United States for release April 14.

The Old-time Prejudice of the Fruit-growers against Bees Practically all Gone

EVERYWHERE we go throughout this great West we find that the old-time prejudice against the bees, on the part of the fruit-growers, has practically disappeared. It exists in a few sections among the ignorant and those who would naturally be prejudiced against any industry except their own. All up through the great orchard districts of Oregon, bees are coming more and more into demand. We find the same thing in California, especially in Santa Clara County. The growers of prunes and apricots are especially friendly toward the bees, and are inviting the beemen to put bees in their orchards everywhere.

There was one little section in Oregon where some of the apple-growers were foolish enough to set out syrup poisoned with arsenate of lead to kill bees. They succeeded all right, and destroyed large numbers of them, practically ruining all beeyards of the vicinity; but that foolish prejudice has practically disappeared, and, so far as we know, there is no more poisoning of bees.

There are other localities where bees are not thought to be essential to proper fruitage. The following is a case in point:

An Apple-orchard of 15,000 Acres in the Pejario Valley, Cal., where the Trees are Sprayed while in Bloom: Some Astonishing Revelations

IN connection with Prof. C. W. Woodworth, of the University of California, situated at Berkeley, we visited one of the most famous and perhaps the most extensive apple-growing region in the world. In a little area in the Pejario Valley, with Watsonville as a center, there are shipped out annually 4000 carloads of apples. The whole area comprises something like 15,000 acres, nearly every foot of which is devoted to the growing of apples. The only varieties grown are the Newtown and the Bellflower. Other fruits, such as strawberries

and Logan berries, are grown in that valley that will aggregate nearly 4000 carloads more. Just think of it—8000 carloads of fruit from a triangular region about ten miles across!

But what has all of this to do with bee-keeping? At first we heard that there were no bees there. If that were so it would have a tendency to contradict some of our theories concerning apple-growing; but investigation showed that there were some bees in the valley, just the same, although the number was comparatively small; and the strange thing is the fruit-growers in that valley, supported by the county horticulturist, do not care to encourage the introduction of bees. Another remarkable fact is, that the *trees are sprayed while in bloom*; and the horticultural commissioner, Mr. W. H. Volek, supported by Prof. Woodworth, says that *such spraying does not kill the bees*, and they do not believe that the spraying of cover crops in Colorado would do it either.

Right here locality has a wonderful bearing on the relation of bees to apple-growing. Both varieties of the apples mentioned are self-fertilizing in that valley—that is to say, they do not need the agency of bees to mingle the pollen. At least in that particular valley it would appear that bees are not an important factor in the production of these two varieties.

One more factor is the long period of bloom during which the bees are able to work. A comparatively small number of bees in weather like that of the valley can do the work of many bees in localities where cold and damp weather allows them to work on the blossoms for only a few hours.

But how do they know that spraying while in bloom does not kill the few bees that are there? Professor Woodworth placed a colony of bees right in the midst of the orchards during the time when the trees were in full bloom, and while they were being sprayed. Instead of using arsenate of lead the apple-growers use arsenite of zinc—a much stronger poison; and even this, say Professor Woodworth and Commissioner Volek, had no effect whatever on that colony of bees. They *prospered during the entire spraying season, and stored honey*. After the spraying season was over, the colony was sent to the University at Berkeley, and both the honey and the bees themselves were very carefully examined for traces of arsenic; but none could be found except on the outside of the bees. It seems that the bees were literally doused with the poison while they were flying; but, apparently, they got none of it in their intestines.*

Commissioner Volek was kind enough to take us in his machine over different parts of the valley. We drove something like thirty or forty miles that day. We found bees in several places, but hardly enough to pollinate such an enormous number of trees provided the varieties were sterile to their own pollen, as occurs in most cases and in most localities. In this connection it appears that locality has a strong bearing on the question of whether bees are needed to pollinate the blossoms. The Newtowns and the Bellflowers are the only varieties that do well there, and both are apparently self-fertile in that wonderful clime.

We remarked that if more bees were put in the valley there would be more fruit; but Commissioner Volek immediately replied, "The fruit is too thick there already as it is. It has to be thinned out on the trees."

"But," we remarked, "if there were bees there in sufficient numbers, would not the fruit be larger?"

"It could not be very much better," he said, and pointed to some specimens on the hotel table where we were then eating.

Professor Woodworth is Entomologist of the University of California at Berkeley, and a great friend of the bees. While he freely acknowledges they are necessary for the proper fruitage in many localities, he says it is clear that their presence in that valley is not essential.

He says, however, that there were more bees there on this tour of inspection than he supposed; and he thought it was possibly true that they did some work in those orchards. But one thing he says is quite certain; and that is, that spraying while in bloom did not hurt the bees nor the fruit. He had his serious doubts as to whether the arsenate of lead that fell on the cover crops in Colorado was the real cause of the death of so many bees. We told him that Prof. C. P. Gillette, of the Colorado Experiment Station, was very much of the opinion that it does kill the bees. That might be possible, but he did not see how locality could make all the difference. Dr. A. J. Cook, Horticultural Commissioner of California, on the other hand, said he was very sure that ordinary arsenate-of-lead sprays could and do kill bees under most conditions, and reports generally seem to confirm this.

* Prof. Woodworth, in an article in GLEANINGS, page 987, Dec. 15, 1914, described the observations and the conclusions he had reached on this matter. Subsequent criticism has been to the effect that experiments with arsenite of zinc would give no result for arsenate of lead, since the former might repel the bees. It was also brought out that one colony one season was not a fair basis for conclusion.

Dr. C. C. Miller

STRAY STRAWS

Marengo, Ill.

I WONDER if the light outdoors is not better for bees in winter than the darkness of the cellar.

Now isn't it funny,
With so little money,
The eating of honey
Makes tempers so sunny?

A CAMPAIGN is getting under way to make Chicago dry in 1916. Are they crazy, or is the millennium at hand?

How good it seemed to see the old-time leaders, L. C. Root, P. H. Elwood, and W. P. Henderson, again in print in *GLEANINGS*, April 1!

ARE you planning to keep tally of every pound or every section you take from each colony this year? If so, then you'll know what stock to breed from next year.

YOU say, Mr. Editor, p. 219, that I can not pack my hive-cover. Why can't I pack that dead-air space? To be sure, it's only $\frac{3}{8}$ inch, but it could be made more. Yet the double telescope may be warmer.

M. A. GILL says, *Western Honey Bee*, 7, that he marked his No. 1 sections "not less than" 12 ounces, and his No. 2 "not less than" 10 ounces. That was considerably less than their weight, but he could sell his honey by the case just the same as before the new law, without running the risk of free board at Fort Leavenworth.

JOHN S. SNEARLY, I use thin super foundation in sections, top starters $3\frac{1}{4}$ inches deep, bottom-starters $\frac{3}{8}$. I don't use extra-thin because the bees are so much worse at gnawing it down if at any time there is a lull in the flow; and even if I should use extra thin above I should want heavier for bottom starters so they wouldn't topple over.

G. M. DOOLITTLE's last way of preventing after-swarms—listening for piping—is excellent, p. 266. For those who might prefer one of his previous plans, let me suggest a slight variation. Leave the old hive standing close beside the swarm for a week. Then, at 2 o'clock, carry the old hive to a new stand. That's less trouble, and just as sure to work as the gradual turning.

USUALLY I go by the blooming of the soft maple in taking bees out of cellar, but sometimes it is not reliable. A little almanac must be mixed with it. This year a few blossoms were out on one tree—and only one—the 25th of March, and the thermometer was up to 55 degrees. If it had not been for the almanac the bees would have

come out. But at once it turned cold—15 to 20 degrees each morning—and it was good to know that bees were in the cellar.

THE question is asked by P. C. Chadwick, p. 264, why is it that in one case bees recover from a three-days' freeze, and in another case succumb in a much shorter time? As a sort of forlorn hope let me suggest that the deciding factor may be the thawing. Take frozen fruit or vegetables. Plunge part of them in a pail of water nearly freezing, and let the rest thaw in warm air. Let the first thaw out slowly, and they will be as good as new, while the latter will be spoiled. Why not the same with bees?

A LONG time I looked with much interest at that picture of the Quinby home, p. 269. One summer in the '60's a business trip took me through St. Johnsville, and I called on Mr. Quinby. He insisted on my spending the night, and I shall never forget his kindly treatment of the budding young beekeeper. His apiary was somewhat picturesque, his hives innocent of paint. In that economy I have imitated him. The first hives I ever had—I made them myself—were Quinby box hives. His instructions in *The American Agriculturist*, continued monthly for years, were always excellent. His book was a revelation.

THE *Country Gentleman* is doing good service in championing sweet clover as a farm plant, but is behind the times on spraying. Its latest number contains an article advising to spray fruit-trees when two-thirds of the blossoms have fallen. [Of late, experiment stations and other authorities on the spraying of fruit-trees seem to be inclining toward condoning, if not actually suggesting, spraying while the petals are falling. At that time the secretion of nectar is ended, the pollen dried up, and few bees are working on the blossoms. Prof. Chenoweth of the Massachusetts Agricultural College says that bees no longer visit the blossoms when the petals are falling. At the Massachusetts Fruitgrowers' Convention last winter, the statement was made, "The blossoms of the trees fall at different times and one cannot be hanging around with the spraying apparatus watching for the proper moment for each tree." To this Prof. Chenoweth replied, "You would have to take the time when the maximum number of trees are shedding their petals and do it then. You would probably kill a few bees, but not enough to do serious damage."—ED.]

J. E. Crane

SIFTINGS

Middlebury, Vt.

Wesley Foster's experience in selling light-weight sections is given on page 9, Jan. 1, is helpful, and can be used to good advantage in a home market.

E. S. Miles, page 70, Jan. 15, has serious trouble with large black ants. Suppose, instead of trying to subdue with kerosene, he tries making a hole six inches deep in the top of one of their mounds, and pour in three or four ounces of carbon bisulphide and cover closely. It evaporates quickly, and its fumes are a deadly poison.

On page 2, Jan. 1, we are informed that the bee-cellars at Medina are inspected daily to determine the temperature of the air, the condition of the bees, and the purity of the atmosphere. Will the editor please tell us how he measures the purity of the atmosphere? [So far, only by our noses and by noting the actions of the bees. —Ed.]

There has been a good deal of discussion in recent numbers of GLEANINGS as to the desirability of making two colonies from one early in the season, after Alexander's plan for securing surplus honey. I notice that those (or most of them) who favor this way have a flow of honey in August, while those who do not favor this method depend almost wholly on clover.

With me, bees that were placed in cellar in November have wintered well, although the temperature has been most of the time above 45 degrees. The winter has been fine for wintering outdoors, but I anticipate some loss because an unusual number of colonies were quite weak last fall. We have had but little severe weather, with an occasional day when bees could fly to their hearts' content.

I think I have read somewhere that A. I. Root and Dr. Miller were trying to live to be one hundred years old. Well, there are possibilities. For their encouragement I just want to say that a man recently died in our town in his 106th year. He was a Methodist clergyman who had retired after preaching for sixty or seventy years, although he continued to perform marriage ceremonies until past 100. He celebrated his 100th birthday by preaching a sermon in one of our local churches.

With regard to the use of tartaric acid, as I said before, I find little use for it when a syrup made of two parts sugar and one of water is used, and I have fed a good deal of such syrup after the middle of October. The only objection to a thicker syrup is that, if it gets cold, as it is likely to on colonies a little weak, the bees are very slow about taking it down late in the season.

In an editorial, page 176, March 1, I read, "There is a certain advantage in having a colony during winter in a nice compact cluster. In that condition there is less activity, less consumption of stores, and no brood-rearing." No brood-rearing! Isn't that putting it pretty strong? Here in Vermont the most of our colonies in double-walled hives appear to be in that condition during the winter; but I do not remember ever opening a strong colony after the middle of February that did not contain more or less brood.

On page 56, Jan. 15, R. F. Holtermann asks if the fence around a yard of bees to which I referred some time ago is eight feet high. I could not say. It was many years ago that I saw it, and I think the fence was not more than six or seven feet high. What is more, I believe the hives were single-thickness board hives, which might make all the difference in the world. With ten inches of packing, such as they are using at Medina, I should not think the bees would get warmed up enough to fly until it was safe for them to do so. Indeed, if they could tell when it is spring I think they would do very well.

It almost took my breath away to read the editorial, page 48, Jan. 15, about sweet clover in the three counties of Kentucky. Wouldn't that be great—white clover through the month of June, and then sweet clover till late autumn? That must be the paradise of beekeepers. But when I read further on that there are already 4000 colonies in one county I began to feel as a lady did who wanted to go into the hotel business. She said she thought she would wait till everybody died so she would have no competition. Perhaps a given number of colonies will do no better there than here. But at any rate it shows us beekeepers how we ought to stimulate the growth of sweet clover where we are.

BEEKEEPING IN CALIFORNIA

P. C. Chadwick, Redlands, Cal.

Bees in the city are beginning to swarm. This is about as early as I have ever known swarming to begin to any extent.

The first orange-blossoms of the season opened in this locality about March 25. The main blooming period will not be on for two weeks.

When I looked at the picture of foul-brood combs on page 235, March 15, I felt like grabbing them up to put them out of the reach of bees.

Filaree does not seem to be yielding its usual quantity of nectar this season. The quantity of pollen from it is becoming a nuisance in the combs.

A writer in the *Western Honey Bee* says Nevada honey sells from one to three cents higher than California honey. On that point I am from Missouri.

I have one colony with brood in three supers, seventeen frames in all, and still spreading. I would try the much-discussed spring dividing on them if it were not that the orange is already beginning to bloom.

The "boss" slipped in on me last week. Gee! but I felt nervous. After he had gone I felt foolish over my fright, for I now have his personal permission to call him plain Ernest Root. Such a warm, open-hearted man! just one of the boys.

In a private discussion while at the state convention, on the question of whether or not bees hear, I voiced the opinion that they do hear. Since that time I have studied the question a little deeper, and have come to the conclusion that I was foolish indeed to entertain even a thought that they might not hear. Really their actions in the air, while swarming, and at nearly all times, are controlled by the different sounds of their wings, which is talk to them.

While passing the hospital on March 23 I saw a large swarm of bees entering that institution. There was no ambulance in sight nor doctors in attendance. So far as I know they were not diseased, nor really in need of medical attention. Perhaps they

are to assist the rheumatic patients. As they entered near the busiest part of the building it will be almost safe to say they will operate on some one before long.

On March 13 I found a two-story colony trying to raise brood in an upper super that was nearly full of honey. To relieve them I reversed the supers temporarily. The result was five combs full of eggs and larvae on the 23d, in addition to what they had on the 13th.

In the *Western Honey Bee* for March, Editor Bixby gives C. I. Graham a beautiful coat of whitewash, and closes an editorial by saying that all Mr. Graham asks for is a square deal. That is fair, perfectly fair; but Mr. Bixby would have a hard time in convincing a large number of beekeepers other than that, if Mr. Graham had had a square deal, he would not have shipped half the bees that he has been given credit for having shipped.

The school exhibit of the tri-counties fair as pictured on page 238, March 15, is interesting to me. We watch the little folks grow and develop, and wonder what their "bent" will be. They are a great study, and should be given some latitude of action so that they may choose a line of work for their future which they like, and are in turn of mind adapted for. One of the chief problems with boys of this day seems to be to steer them clear of the cigarette habit. With the girls it is to impress them with some sense of modesty.

Prospects are indeed bright, but we should not be too sanguine, for just such fine prospects have turned into disastrous seasons within a short time. A few days of hot dry desert winds and a dry spring will change the situation entirely. The best time to measure the honey crop is when it is ready to market. The ground is wet deeper now than at any time last year; and with sufficient surface moisture during the spring, with no desert winds, we should get some honey. The sage is a problem to me this year. It looks well—in fact, as well as I have ever seen it; but since it yielded well last year, and we have never to my knowledge had two successive good yields from the sage, it makes me feel a bit doubtful as to the outcome.

BEEKEEPING IN THE SOUTHWEST

Louis H. Scholl, New Braunfels, Texas.

That cover picture of Ira D. Bartlett's apiary, in the Feb. 1st issue, appeals to me from the fact that it shows the hives arranged in pairs. I have raised my objections at various times to the too common practice of placing them in long rows with a single hive to a location, and all the same distance apart. My experience seems to prove beyond a doubt that the loss of queens returning from their mating-trip is far greater because of the fact that the queens are less able to locate their own hives when they are all alike. This is obviated to a great extent by setting them in pairs, even when they are in long rows. I prefer to have them in groups of fives, partly in the shade of a tree or where there are several trees close together, facing three hives to the southeast, one to the southwest, and another on the opposite side facing to the northeast. Enough room is left between the backs of the hives and the tree or trees to allow free operation with the hives from the rear, and out of the flight of the bees. I call attention to this matter at this time so that others may try it when setting out their bees this spring in the North, or for those who may wish to rearrange their apiaries in the South. I have had several enquiries on this subject lately.

"BUY MORE COTTON" OR "BUY MORE HONEY"?

When the cotton farmer was so "hard hit" by the outbreak of the European war every effort was made to relieve the strenuous situation that affected almost every industry and every vocation to some extent. One of these movements was the "Buy a Bale of Cotton" idea, and many bales were taken care of in this way.

The writer soon learned, not only from his own experience as an extensive producer, but from many other sources, that the beekeeper is suffering from the effects of the war upon the honey markets, especially in the South. It was soon realized that the beekeeper, as a producer, was affected very much as was the cotton producer; and if the "Buy a Bale of Cotton" movement was doing the latter some good, why should not a "Buy a Pail of Honey" movement aid the beekeepers?

It is not too late for a campaign of this kind even now. There is much unsold honey, and the end of the war is not yet; so that I feel the conditions will not meet with

a material change for the better for some time. Especially true would this be if we experience another large crop this year, for which the prospects in Texas, at least, are most excellent.

THOSE COVER PICTURES.

Speaking of the cover pictures as they have appeared on the front cover of GLEANINGS for some time, I agree fully with Prof. Newell, p. 134, Feb. 15, in hoping that this type of cover may not soon be discontinued. These not only help to make GLEANINGS look more beautiful, but the pictures the editors have used have been interesting and of an instructive character in one manner or another.

With special reference to the illustration of the experimental apiary near College Station, Texas, by Prof. Newell, I feel that Prof. Newell would not have the readers, and especially beginners, infer that he would have them adopt in their own apiaries either the arrangement of the hives, the methods of keeping records, and one or two other features shown in this picture. I have already raised objections to setting hives singly and systematically in rows or in hexagonal order. This experimental apiary is arranged in this manner.

Although the manner of keeping records of the hives as shown is excellent for experimental purposes, it would be rather impractical to employ on a large scale or for many hundreds of colonies. While the white-painted and numbered-stake plan is a good one in some respects, the stakes are rather expensive in the first place; and in keeping up the numbering properly on account of the comparatively rapid decay of stakes driven in the earth I should prefer to keep the number of the location on the hive-body itself, and for this purpose I have a hive number that surpasses any that has been brought to my notice so far. This has been shown in GLEANINGS, but it seems to me it was not fully understood. It is very simple, made of galvanized iron, is very cheap, easily made, and hangs over the hive rabbit, and is held firmly in place by the supers or cover set on it. It is easily shifted from one hive to another when there is occasion to take the hives to another location. These are more satisfactory than the stakes, and are not in the way of the operator.

The manner of indicating certain conditions of the colonies by means of bricks on

top of the hive-covers is an old plan that I once employed myself while carrying on experimental work at College Station, and I had hanging in the honey-house a chart showing the meaning of the different positions of these bricks on the hives. The first cost of the bricks is rather expensive, however, and it is a lot of trouble to lift off and replace the great number of heavy bricks every time a hive is to be examined. Of course, the argument may be advanced that these bricks serve the additional purpose of holding down the covers against being blown off by strong winds; but I have preferred the use of slightly heavier covers, or such that are so constructed that they can not be blown off easily, and that can be lifted off with one operation. I still adhere to the manner of indicating the condition of the colonies on the hive-covers, but use small stones or pebbles that can always be picked up in almost every apiary. These cost nothing, and serve the purpose just as well.

* * *

THE EMERGENCY AND GENERAL TEXAS FOUL-BROOD APPROPRIATIONS.

Governor Ferguson has just signed today, March 18, the emergency foul-brood-appropriation bill of \$3000. This is purely an emergency appropriation for this year, and to precede the general appropriation requested by the Texas Experiment Station in the budget for the next two fiscal years beginning Sept. 1.

No appropriation was made by the Thirty-third Legislature for this purpose, owing to the fact that this was by some mysterious manner left out of the appropriation budget altogether during its passage through the legislature. Owing to the fact that the general appropriation would not become available until after Sept. 1, this emergency appropriation will permit the work to be taken up again immediately where it was left off over a year ago.

The amount asked for in the budget of the experiment station is \$10,000 for each of the two fiscal years, 1914-'15 and 1915-'16. This is a larger appropriation than has ever been asked for such purpose, or that has been made by any other state. It is intended to use a larger amount of money at one time with the determination to eradicate the disease from the state rather than to carry on the inspection work in the usual and more or less inefficient manner year after year with smaller appropriations. It is believed that this will prove by far the better plan, and cost less eventually. With the disease once wiped out, proper quarantine regulations established and enforced,

and then followed up with smaller appropriations more easily obtained thereafter, seems to be a superior policy with which to cope with the monstrous task of dealing with foul brood.

Although the members of the present legislature have begun to understand the great importance of the beekeeping industry, and the great need of ample appropriations of money with which to combat foul brood and other bee diseases, it is impossible at this time to say whether they will grant as large an appropriation as is sought for this purpose in the experiment-station budget. If they only knew the gravity of this question, and the effect the presence of this disease has in retarding the beekeeping industry, there would be little hesitation. Most of the members know little or nothing about this matter. They are not beekeepers; and even many who have bees of their own, or those who have neighbors who may be even extensively engaged in this pursuit, do not know the seriousness of the situation as we do. It behooves us, therefore, as I have said in this department before, to call their attention to it. The appropriation bills will come up in the special session, which convenes April 29, and there will be plenty of time for Texas readers to write to their representatives and senators after they get this journal, and before the legislature meets again. Even if one has already written them, it will be well to call their attention to it again for the special session.

In conclusion I feel grateful indeed to the members of the Thirty-fourth Legislature for already so willingly granting the emergency appropriation that is now available, and I hope they will give further due consideration to the regular appropriation.

* * *

BEEKEEPERS AND LAW-MAKERS.

The Texas legislature has at least one beekeeper among the membership this year. "Beekeeping" is given as the occupation of this member, and I know that this is the sole occupation because I happen to be that member. It has always been my utmost endeavor to place beekeeping on a higher plane, and much of my time has been devoted to efforts in this direction during the last fifteen years. Of course, to many it will occur as to whether "mixing beekeeping with politics" is lifting our beloved industry to higher planes. I would have it understood, however, that I do not desire to be classed with the "professional politicians." It is my desire to remain just a plain common-sense representative of the people who have chosen me to represent them.

CONVERSATIONS WITH DOOLITTLE

At Borodino, New York.

QUESTIONS ANSWERED.

Can you tell us how a queen makes the noise in piping? My neighbor beekeeper says that the noise is made with the wings, but I am somewhat in doubt.

I have watched virgin queens many times when they were in the act of piping, and never yet saw one standing up with wings "purring and fluttering," as I was told they did when I first began keeping bees. One day, when I heard a queen piping quite vehemently, I carefully lifted the frames till I came to the one she was on. In later years I found out that such careful lifting is not required; for when a queen is really in earnest she will go on with her noise, even when the frame she is on is handled quite roughly.

A piping queen does not stay long in one place, but is like the seventeen-year locust which sings her song on a limb of a tree and then goes to some bush or fence-post to sing the same song over again. So the young queen will run about among the bees for a little, when she will suddenly stop and crouch upon the comb till she apparently lies as flat as possible, when the head is slightly inclined upward, or off from the comb, and the piping sounds uttered. This seems to require considerable effort, as there is a tremor throughout the whole body.

From almost hours of watching I have never known any queen to pipe unless she stopped and thus arranged herself on the comb, nor have I ever heard a "pipe" from any queen while she was on any other place than a comb. I thought the comb was necessary, so that the feet might lay hold on the inside of the cells, but had to give that up, for they perform this operation on smoothly sealed honey, or on sealed brood with apparently the same effort as on unsealed cells. I never saw a queen pipe without a slight incline of the head upward, nor without an apparent stiffening of the whole system and a slight tremor of the body.

Just how the noise is made I was always at a loss to know. The noise sounds very much as if a tiny saw were wrestling with a tiny splinter, only the first noise is much longer drawn out than those which follow. Then the interval between the first and second notes is much longer than are those which follow in rapid succession up to five or six, according to how long the queen has been piping, and how enraged she becomes from the quacking of one or more queens in their cells which are being held as pris-

oners there, awaiting the issue of a second, third, or fourth swarm. I have no idea as to how the queens quack in their cells; but certainly this cannot be done by any fluttering of the wings. Who can tell us more?

How can I tell whether a colony has a laying worker? I am told that such workers lay only in drone comb. Is this right?

Doubtless laying workers use drone-cells more largely than they do worker-cells, but they will use either, and more often prefer a queen-cell cup than any other kind of cell. Then laying workers generally place more than one egg in a cell, while a fertile queen rarely ever lays more than one egg in a cell, unless it is at a time of few bees in early spring with a sudden and generous supply of pollen. At such times a prolific queen will often lay two or more eggs in a cell. But no one who has carefully examined to know how a prolific queen places her eggs in the bottom of any cell, with each standing on end as if glued there, will be "caught napping" regarding the eggs of laying workers. They attach their eggs in all manner of ways to the sides and bottoms of the cells, and often put from three to ten in any queen-cell cup that may happen to be in the cluster of bees where such are laying. Then these eggs lie about in different angles to the base of the cells, so that even the inexperienced have a suspicion that something is wrong.

Are large colonies more liable to swarm than small ones? I am told that they are. But I read that large colonies are needed to get good results in surplus honey.

I think there may be a misunderstanding in this matter regarding large colonies. With a large hive, say one holding twelve Langstroth frames, or a hive containing 2500 to 3000 cubic inches, a colony in such a hive will not be as much inclined to swarm as will a colony in an eight-frame L. hive, or one holding 1800 to 2000 cubic inches. Now, in the usual way of speaking, any colony in the large hive will be called, four times out of five, a large colony, while the one in the small brood-chamber would be called a small colony; and under this rendering the small colony will be more likely to swarm than the large one. But with the same proportion of bees as to the number of cubic inches, I have never been able to see much difference as to the inclination toward swarming. Of course, with each hive proportionally filled with bees, the swarm issuing from the large hive would be large.

GENERAL CORRESPONDENCE

THE HIGH AVERAGE OF SUCCESS IN BEEKEEPING

BY CHALON FOWLS

Of the recent special numbers of *GLEANINGS* I have enjoyed none more than the one giving the experiences of old beekeepers; and I consider the article by Ira D. Bartlett one of the very best. In reading how he worked up the business from nothing to five hundred colonies one grows enthusiastic about the possibilities of beekeeping, and we suppose the confiding and optimistic imitators will expect to read at the close something like this: "Go thou and do likewise." But, alas! we read, "It is said ninety per cent fail in the business." O Ira! how could you? Now, "honest Injun," did you ever believe that rot? Well, I never did, and I am getting tired of hearing such loose statements referred to as though they were established facts, and I will undertake to show that in my locality, at least, such a characterization of failures in beekeeping is wide of the mark.

In the first place, what constitutes a beekeeper as the term is used in our journals? Manifestly, it does not mean a person who owns a dozen colonies or less. As well call every farmer who has a like number of hens a poultryman. There are many farmers who keep a few bees who have a hundred times more capital invested in their farm or stock, and also spend a hundred times as much labor on them. So I will leave those out of the calculation.

But in our own county (which I consider an average one for this part of the state) during the thirty-five years since I commenced, I can recall only twenty who have had forty or more colonies, and of these only two I would say did not succeed. And these failures I would attribute to the men and not the business. Of the others, five have been removed by death, three discontinued on account of old age, two sold out their bees to engage in other business, and eight are still engaged in beekeeping, and are making it pay. Of the latter, all but two have combined general farming or fruit-growing with beekeeping. It follows, of course, that their attention was divided between the occupations. Yet, although these were not true specialists, there is no question of their success. I cannot give figures to show just what profit these sixteen men made for the time and capital invested; but as I was personally acquainted with most of them I know they were

making it pay, as may be inferred from the fact that they still keep their apiaries, or did until old age or death intervened.

I do not claim that this list is complete, as there may be others living at some distance from me that I don't know of; but I have no reason to suppose that the addition of such beekeepers to my list would make the average very much different. Of course, just as in raising other food products there are some who make a better showing than others. But I believe a large majority are making more money for the time and capital invested than is made in most of the other lines of food production.

Looking to the future, I consider the outlook good, both for securing good crops and realizing good prices. Here in our locality in the past our crops have been principally white clover and basswood; but now, although basswood is nearly gone the loss is more than offset by the increase in alsike clover, which so far has never failed to furnish a crop of honey.

But it will be argued, if people are encouraged to engage in the business will not there be an overproduction that will ruin the market so that a person cannot be sure of making a living at the business? I answer, no. The consumption of honey is increasing much faster than the population, and I think a very large part of our future market is yet undeveloped. We have a lot to learn yet in the way of advertising. As a pointer to show an awakening of interest in our product I will mention that I have just received an invitation from a large jobbing house to give an address on bees and honey before their traveling men. This was entirely unexpected and unsolicited. Of course I accepted. I told them I would be "delighted." This, of course, shows that the great jobbing houses are becoming interested. Then the local or home trade shows just as healthy growth. It is a fact that there is more honey sold at one store in my home town now than there was in the whole town (with perhaps a dozen stores) thirty years ago.

Some are in the habit of saying that honey at present prices is too much of a luxury to come into general use with the masses. But what about the breakfast foods? It strikes me that ten cents a pound is a pretty stiff price for wheat; yet the

Government apiary at Somerset, Md., showing the electric cables used in recording temperature, wind, velocity, etc.

masses are paying it, and why? Because they are coming to believe such preparations are healthful, and they will use honey for the same reason when it is properly brought before them. I understand there has been a large increase in the production of extracted honey of late years, yet I do not find it has resulted in lowering the price. Referring to the market reports in GLEANINGS, I find the Cincinnati market report for February, 1915, for clover extracted in cans, ten cents; February ten years ago, seven to eight cents; February twenty years ago, four to seven cents. Although this does not show all the fluctuations, it is a fact that the prices are better now than twenty years ago.

To show further my faith in the business I will say that my son, a young man of twenty-four, is giving up a good position in the city to engage in some outdoor employment, and, with my encouragement, he will take up beekeeping. Shall I tell him that ninety per cent of those who engage in this business fail? No! I would rather quote from an optimist like my old friend H. R. Boardman. In a private letter that I received from him during the past year I find these words—and I am sure he will not object if I quote them here: "If I were only a young man of twenty I would just be delighted to engage in beekeeping."

Oberlin, Ohio.

THE ELECTRIC CONNECTIONS IN THE GOVERNMENT APIARY, WASHINGTON, D. C.

BY E. R. ROOT

The accompanying illustration gives a view of the Government apiary in the suburbs of Washington, D. C., at Somerset, Md. The reader will notice sundry wire cables running to the quadruple packing-case containing four colonies, and to the two or three single-walled hives, each containing a colony. These cables are connect-

ed with electric thermometers from which readings are taken, taking the internal temperature of the colonies. The hives in the background comprise the regular Government apiary; but these are not connected with the electric apparatus for recording temperatures. Just a little to the left of the quadruple packing-case, and in line with

the evergreen, is a Government anemometer. Electric wires run from this to the building where records are taken of the velocity of wind, because this has a great deal to do with the wintering problem and with the internal temperature and external temperature, as well as with the temperature surrounding the cluster of a colony of bees.

The little latticed structure shown in the right foreground is what is called a "weather-bureau shelter." Its purpose is to pro-

tect weather-bureau instruments from sun and rain, and at the same time leave them subject to direct atmospheric changes. One of the instruments is a thermograph for recording temperatures, and the other a hygograph for recording humidity. These outside weather conditions are used for comparison with the internal cluster temperatures as taken through the cables to the hives and recorded inside the office.

THE ISLE-OF-WIGHT DISEASE; HOW IT MAY BE HELD IN CHECK

BY A. H. BOWEN

There are few English counties in which the dreaded Isle-of-Wight disease has not appeared and spread with unabated vigor, and fewer still are the hives it has left intact after its deadly course has been run. Moreover, it takes all the skill and energy of the large hive-owner to keep on keeping bees in spite of it. It seems useless to wait patiently for the perfectly immune bee to turn up; for while this is being done the malady is getting ahead of beekeepers, and devastating their apiaries right and left.

There is little hope of a permanent cure being established, for the simple reason that no one knows he has the disease until the bees are flopping about on the ground and dying rapidly in front of their hive. Stocks in such condition are beyond any possible treatment, and few there are indeed who can detect the trouble in any earlier stage than this. Usually the strongest and best colonies succumb first, owing, no doubt, to the greater amount of diseased honey that is brought home; and the apiarist who is well informed on diseases could, by watching carefully the first few crawlers, with abdomens swollen and wings split, collect enough evidence to prove the case without waiting for the bees to die by the hundreds before the colony is destroyed.

It would seem that the greatest move that can be taken in checking the spread of disease is to tackle the means by which it is conveyed from hive to hive and apiary to apiary. Beebooks tell us that the Isle-of-Wight malady is spread by the water in pools and other drinking-places where healthy and diseased bees are wont to visit; by the passage of drones from infected to clean colonies by the carelessness of the owner in not keeping himself or his tools thoroughly disinfected; and also by robbing. For myself I have enough evidence to convince me that robbing is responsible first, last, and every time.

Since the days of the old straw skep the keeping of bees has increased fourfold. Both hives and apiaries are more numerous than ever; and in favorable localities they follow each other in a continual chain running for miles. When the Isle-of-Wight disease appears it soon spreads from one to the other, and in a manner that shows plainly that robbing is responsible.

As soon as a colony is first attacked by the Isle-of-Wight disease a general disinclination to work becomes noticeable. The bees loiter about on the alighting-board, and the hive is no longer the scene of activity it formerly was. Soon the colony dwindles, at first slowly and then more rapidly, until none but the youngest bees are left.

The combs are generally full of stores, and a hive in this condition contains enough disease germs to infect a county. Frequently the unsuspecting owner sees nothing amiss until the stock is set upon and robbed out completely. Sometimes the trouble is noticed; but the beekeeper—loath to destroy the few hundred bees that remain—leaves the stock alone, hoping the bees will pull round; and so the robbers do the work that he himself should carry out. Quick action is what is needed most. When a hive shows the first symptoms of disease the bees should be destroyed, and the entrance closed securely until the interior can be dealt with properly.

This can be done with cyanide of potassium, or by a charge of lighted sulphur burned under the frames. It might be worth while to use sulphur and so save the honey, as cyanide renders it poisonous. The combs can be rendered into wax; but the dead bees, quilts, frames, etc., must be burned, and the hive thoroughly disinfected.

The chief means of infection is thus quickly removed before harm follows, and it may be that this will end the trouble—if not permanently, at least for some time. As

A Cheltenham skeppist and his home where honey is retailed.

regards precautions it is better to have many apiaries of a few colonies than many stocks in one apiary.

With bees scattered, it is much easier to control the spread of disease, while there is always a chance of getting a crop of honey from the healthy stocks. The common practice of exchanging brood and super combs at extracting or any other time is to be condemned. It is a simple matter to number both hives and supers, and return the combs to those from which they were taken.

Syrup fed to the bees should always contain some strong medicinal agent, while the best winter food for disease resistance is sealed honey and medicated syrup, half and half. Izal is reported to be an excellent preventive of disease, and useful as a disinfectant for washing out hives, etc.

It is the duty of every enlightened beekeeper to hunt up his neighbors to see if their bees are clean or diseased, and to help them in applying the same treatment or precautions that he himself is taking. Happily there are signs that greater care is being exercised all round; and if the Isle-of-Wight disease has the effect of waking up beekeepers to their full responsibility, the losses through this and other causes will

be reduced to a minimum, and it may yet prove a blessing in disguise.

A HILLSIDE APIARY.

One of my out-apiaries on the Cotswold Hills is situated in the heart of the sainfoin country, and the honey is very light in color and of a most delicious flavor.

We get but few bee-flowers till May is out, so plenty of honey in the autumn is necessary to carry the bees through the winter and early part of the year. A sheltered position and a good honey-house are two things of importance in out-apiary management, and this yard is well situated for both.

The other picture is that of a quaint Cotswold cottage, the home of a skeppist whose rustic bee-garden of straw hives is to the right of the house. This is also the village postoffice and general store, where quite a lot of honey is retailed over the counter.

Every lover of nature enjoys the Cotswold Hills with their delightful views and picturesque hamlets. An air of quietness always seems to rest upon them, and they are far enough away from towns still to retain much of their rustic beauty.

Some of my pleasantest memories are of the hills on the hot, sleepy afternoons of summer with the rich flat meadows and

An air of quietness belongs to the Cotswold Hills.

bare green downs in the distance, where the brown cattle chewed noisily around me, and the weeds wavered darkly and indistinctly in the bed of the stream by the old mill.

There was a little wood through which the water flowed, and one could esconce himself behind bushes, while the trout leaped out at river-flies, and the reflected leaves shimmered in the pools.

At last the long day would wear to a close, and the water ripple on, golden in the sunset, with wonderful reflections and dark-green shadows. Then one would wander back to the high road through a peaceful stillness in which the buzzing of insects and the movements of the cattle seemed almost painfully loud, and while the last beams of sunset caressed the dark pool beneath the glimmering weir.

Cheltenham, England.

EDUCATING THE PUBLIC TO THE USES OF HONEY

BY HENRY REDDERT

The average person knows too little about honey. Some time ago I had a conversation with a honey-dealer who disposes of about a million pounds a year. Among other things he said, "It is true that not enough honey is used by the public, considering the production." The greatest amount of honey consumed in this country is handled by dealers and brokers. They set the price according to their sales. How shall we educate the public?

We see large posters on fence and billboards lining the city streets and country roads, advertising syrups of all kinds, newspapers and magazines advertising the merits of sweets for the use of the household, but seldom if at all does one see a sign of

any kind lauding the uses of good pure honey. If it does, it is always in connection with some concoction. No wonder people know of honey only as a cold-cure or the like. This cold-cure business is not big enough to consume the large bulk of honey produced every year, neither does it convince the public that honey is a food.

If honey could be placed on the table of every family, and used as other sweets, as it should be, no beekeepers would have occasion for complaint as to the disposal of their crops at a fair price. In small towns with only a few scattering beekeepers, and the inhabitants of average intelligence, the honey produced can easily be disposed of;

but in large centers of population people know of honey only by hearsay.

Here lies the key to the problem. Who will open the eyes of the public? How can we teach the public that honey is the best of sweets? How can we make them understand that children fed on honey instead of glucose and the like will have stronger kidneys and be healthier as they grow up? I'll answer the questions. The

farmers' institutes, through the farm and home journals, and county and agricultural papers, should push the uses of honey in all cases where sweets are consumed. Teach the students in colleges and schools that honey is the one true sweet that nature affords, which cannot go wrong if properly used, provided it is well ripened and seasoned by the bees.

Cincinnati, Ohio.

THE "OUTLAW"

BY HIMSELF

On Christmas day, 1914, I took a walk in the park and noticed that there was considerable eucalyptus in bloom; and, although the day was a little chilly, still there were quite a few bees at work on the blossoms. I examined some of the bloom and found that they contained drops of honey almost as large as drops of dew, proving that, for the eucalyptus, warm weather is not essential to the secretion of honey. The walk

which I, in my desire to avoid trouble with the authorities, was at last forced to cache my hive of bees on a roof.

The year has been a fairly prosperous one for me. My one colony was increased to three; and while I did not give them the attention that they might have had, by reason of the difficulty involved in obtaining access to the spot where the hives were located, I nevertheless secured something

like 150 pounds of comb honey, this honey being in the form mentioned in another article.

But to finish the day, this Christmas of 1914 I went up on the roof and overhauled the bees (think of that, you anchorites of the snow-bound North). I found that one of my three colonies was at work. This colony was doing quite a little comb-building and storing considerable honey. I took off three frames, a total of about twelve pounds, from that colony. This honey had been gathered within the previous six weeks,

The outlawed apiary, far from prying eyes.

also brought to my own mind the fact that, while I again became a beekeeper by the merest accident, yet I have as much interest in bees as ever.

It is now a year since I related the manner in which I became a beekeeper by finding the small after-swarm on the peppertree bough; of the city ordinance prohibiting the keeping of bees; and the manner in

and by one of the increase, the queen being a daughter of the queen in the original colony. The two other colonies seemed to be loafing and were storing no surplus.

As to the picture, perhaps some person may take me to task for the manner in which the hives are arranged. To such I wish to say that the arrangement or position shown in the picture is not the regular

position that they occupy, but is just a pose that they assumed for the occasion, the reason being that I could not get them all in the picture when the hives remained in the position they regularly occupy. So I moved them up together so that they could have their pictures taken and all appear in one family group.

As to the coming season, I have decided (that is, for the present at least) that I will increase from the three colonies to six, and have been debating in my own mind from which colony to rear queens for the increase, and have about decided that they shall be from the old queen. While it is true that, at the time of writing this, the

old queen has produced no surplus honey for a period of two months, and that one of her daughters has been doing good work during all that time, the question still remains in my own mind whether the mother is not more apt to produce queens the equal of this daughter than is the daughter to produce queens of her own equal. I will state, though, that I am still open to conviction; and if some of the wiseacres can convince me that I have better chances of obtaining queens of the desired quality from the exceptional daughter than from the mother, I am ready to change my contemplated procedure.

SWIET CLOVER ON PEATY SWAMP SOIL

Two Good Crops the First Year from the Seed

BY HENRY STEWART

For a number of years I have been producing sweet clover mainly on peaty swamp soil. Those familiar with this soil know that it is usually very deficient in potash, is very loose, and ill adapted to raising other crops; but we have here no soil on which sweet clover does better. In February last, Stewart & Hansen seeded fifteen acres to white sweet clover. The soil was very loose and ashy, and some of it so deficient in potash as to produce no corn without fertilizing. This seeding was done on oat stubble by simply scattering fifteen pounds of unhulled seed per acre on the snow—no inoculation, no fertilizers, nothing—only scattering the seed. The stand was perfect. The soil on four acres of the fifteen was extremely loose and ashy. On this section during the severe drouth in May and June the plants suffered severely. The first cutting was merely clipped to destroy the weeds, and left on the ground. The rest, when cut July 13, was a heavy stand and stood from twenty to thirty inches high. When the second cutting was made, September 20, the plants on the loose section had developed their roots and were thrifty, and yielded a fair growth of choice hay. On the rest of the field there was a growth even larger than the first cutting; in fact, it was too large. It was the mistake we made with each cutting in letting the growth get too large and begin to become woody. The first cutting should have been made as early as July 1, the second in August, and the third in October, and we would have secured a better quality of hay and a larger tonnage.

I have been seeding sweet clover with

oats on this loose ashy soil for a number of years. It does not always secure a perfect stand, but it always produces much elegant fall feed; and with a good stand and favorable weather conditions it frequently affords a good cutting of hay. When the roots are fully developed on this loose soil, nothing will beat the rapidity of its growth. Many fully developed stalks will attain a height of ten feet.

Our peaty loam ranges from two to six feet deep with a clay subsoil; and, as is always the case under peaty loam, this subsoil is very rich in potash. I may be wrong in my conclusions; but it is very clear to me that the reason why sweet clover can thrive and make such a wonderful growth on this peaty soil on which other plants fail is owing to its deep root system. While surface rooting plants are famishing on this loose soil for want of nourishment and moisture, sweet clover with its deep roots is thriving on an abundant supply far below the reach of the roots of other plants. The root system of sweet clover is enormous. There probably is no field-crop plant that will send its roots so deep and so completely fill the ground with roots as will sweet clover. This whole root system dies the second year of the plant's life, and goes back into decay. If it is true that this root system is built up from potash secured from the subsoil, and from nitrogen secured from the air, then the decay of these roots must not only add nitrogen but must also add potash and other mineral elements as well, and will materially help the soil to farm out and become better, as soil experts

tell us is the case from decaying plant roots on shallow peaty soil.

There is a thought here worth considering; for any plant that will work our potash-mines free of charge, and produce profitable crops, will go a long way toward reclaiming the fertility of this land, and beats securing the potash from the German mines at the present war-time prices.

DIFFERENCES IN GERMINATION OF GOOD SEED.

Last winter I became very much interested in testing sweet-clover seed for germination. I secured as many samples of seed as I could, and secured germinating tests from them. It was really interesting, as but few of these showed a germinating test of 50 per cent, and some as low as 20 per cent, but it was clear that this was not caused from poor seed, as there was practically none rotted; but the ungerminated seed was as hard as little bullets. I soaked one sample for six weeks without phasing this hard seed. I then removed some of the seed and cracked the shell, and in three days they were swelled to three times their original size, and sprouted. I secured one sample, however, that in three days showed a germinating test almost perfect. I pro-

cured some of this seed and seeded with oats and secured an elegant stand.

Now there is no question about the great difference in seed, and that this hard seed has much to do with poor stands on spring seeding. But that this hard seed can not be considered poor seed, there is no question; but the question may be, "Which is the best?" The possibility is that each is best in its proper place. For spring seeding I don't believe there is a question as to the superiority of the easily germinating seed.

For ages sweet clover has been an out-cast, and it has been a case of the survival of the fittest. In its wild state the seeds of sweet clover fall on the ground in August and September, and but very few of them germinate, but they lie there, resist the rain and sun of autumn, and, like heartsease and many other weeds, do not germinate until spring. It is barely possible that for pasture or for permanent growth this hard seed may be a blessing in disguise. The easily germinating seed may all germinate out of season, and the tender plants be killed by the frosts of winter.

There are many things about this new but old plant yet to be fully understood.

Prophetstown, Ill.

EFFICIENCY IN APIARY OPERATIONS

How to Do and How Not to Do. II.

BY R. F. HOLTERMANN

Fig. 1 shows two students standing over a hive. One is smoking the bees, the other removing or inserting a comb. They are standing. To do this with one hive would probably make no great difference, although the principle is wrong. But when it comes to do work in this way hive after hive and hour after hour—yes, day after day for a season—it makes a very great difference between this method and the best method.

Fig. 2 shows the one who is manipulating the combs properly seated on the edge of a hive-cover; but the one who is doing the smoking is standing—a waste of energy. But he is doing something else which is decidedly wrong. Now let the readers of GLEANINGS, especially the beginner and the thoughtless, not read any more until he looks at the illustration and sees what is wrong. The mistake which will be obvious to many is that the one operating the smoker is standing right in front of the hive, preventing the field bees from entering it. I have had students with me for a considerable

time who, after being reminded of this mistake, still did this; and in confidence let me say that, at very long intervals, when much preoccupied I can be seen doing this my-

FIG. 1.—Standing up—a waste of time in the long run.

FIG. 2.—Puzzle picture: Besides standing, what other mistake is one making?

self; but this does not make it any more correct. When a person tells me that something I have done does not square with scripture teaching I always say I am thankful for this much, that my conduct does not change the teachings of scripture.

In Fig. 3 we have things as they should be. Both men are seated. There is no unnecessary energy expended in sustaining the body, and the hands get to the work with as little effort as possible.

Some may ask, "Is not the narrow edge of a hive-cover a rather hard seat?" Yes,

FIG. 3.—Comfortable and convenient—no wasted energy.

but it is always convenient, and is better than none.

I have sometimes thought it would be a good plan to have a light stool, like a milking-stool, with one leg, strapped behind one. When one is working all day in an apiary it would be a great saver of time and trouble. One could then sit down anywhere without any difficulty. There could easily be a stool in each yard, or it could be carried from yard to yard.

Brantford, Canada.

HONEYBEES AS POLLINIZERS OF TROPICAL FRUITS

BY JOHN W. LOVE

The field of flower pollination and the relation of insects to vegetable biology is as intricate as it is vast. It has its traps and pitfalls for the unwary investigator, like those contrived for flies by certain ingenious varieties of orchids. Conclusions regarding the inter-fertility of common fruits must not be accepted unless based upon patient, repeated experiments. With the same caution we must guard against accepting chance assertions made by beekeepers or fruitgrowers in regard to the value of honeybees in the pollination of tropical fruits. Their agency has been firmly established among the common fruits and vegetables of the temperate zone, but, unfortunately, not so firmly among the fruits of the tropics, except the citrus.

An article by Professor E. G. Baldwin on the pollination of oranges was reviewed editorially in the March 15th issue. Two or three bulletins have been published by

the Florida Experiment Station on the pollination of citrus fruits, but these are now out of print so far as I am informed. This is practically all the authoritative information on the subject. Information in regard to other tropical fruits and semi-tropical fruits such as bananas, coffee, cacao (cocoa), cocoanut, figs, olives, and pineapples is very meager.

The blossoms of the orange may be pollinated by the winds; but, like apples, pears, and cherries they are more effectively pollinated by insects, chief among which are honeybees. On dull and damp seasons their presence is necessary for complete setting of the fruit. A number of Florida, California, and Porto Rican growers are keeping bees in their orange-groves for this purpose. The honey from orange-blossoms is most delicious, and has been called "the honey of the gods."

What is true of the pollination of the

National Convention, Denver, Colorado, Feb. 16, 17, 18, 1915. For report see page 217, March 15.

orange is likewise the case in the pollination of lemons and limes, writes Mr. John Barclay, Secretary of the Jamaica Agricultural Society. Although it is extremely dangerous to reach any conclusion unsupported by tests, the guess might be risked that one other prominent citrus, the grapefruit, derives benefit from the visits of honeybees.

Porto Rican coffee-planters are becoming

interested in honeybees as pollinizers of the coffee-blossom. In certain seasons, when there is a great amount of rain during bloom they are particularly useful. The wind will carry pollen only in dry weather; but the bees transfer it in wet weather from one blossom to another during their honey-gathering. According to the Porto Rican Experiment Station, a coffee-grower has

stated that coffee-trees are more productive when an apiary is close at hand than when there are no colonies in the vicinity. Mr. J. T. Crawley, director of the Agricultural Experimental Station at Santiago de las Vegas, Cuba, writes, "I am informed that some coffee-growers keep bees on their plantations with the special view of having the fruit-blossom fertilized." Mr. Barclay

states that bees pollinate the coffee-blossom. No comparative data have been collected. Honey from the coffee-blossom is quite delicious. The bloom lasts only about a day, but the plant is in bloom for a week at a time, three or four times a year.

The banana produces large quantities of pollen, and is freely visited by honeybees. The plant has been called the most prodigal

producer of pollen in the world, one whorl of stamens sometimes yielding enough to be gathered up with a teaspoon. Nectar is secreted with equal profusion, and bees have no difficulty in securing it. Under cultivation the banana is propagated by planting pieces of the stalk and suckers. It has almost entirely lost the power of maturing seeds. When pure seed of a pure-bred plant is desired, so great is the effect of the bees and other insects that it is necessary to bag the flowers.

Bees are sometimes maintained in California almond orchards to pollinate the blossoms. If the grower wishes certain varieties, he should mix with certain others in order to secure the effect of cross-pollination. Very likely locality is important. It is wise to plant with the view both to the desirability of the varieties for market and to their inter-fertility in the locality.

Although part of the palms are pollinated by the insects, the date palm is wind-pollinated in its natural state. For the past four thousand years of its cultivation, how-

ever, man has been artificially pollinating it. The date is an example of the separation of the sexes on different trees, so that self-pollination is impossible.

Apparently the blossoms of the cacao or cocoa tree are not pollinated by bees. Mr. Barclay, of the Jamaica Agricultural Society, states that the blossoms are frequented by small insects which likely carry the pollen; but he is quite certain that cocoa is not fertilized by bees.

The blossoms of the fig are pollinated by a certain special insect of its own, a species of gall-wasp. The uncultivated form of the common fig, called the caprifig, is the male. Its fruit is hard and useless, but is the home of a small gnat-like gall-insect which, in escaping from the orifice, covers itself with pollen. The female runs to the young blossom, which it enters to lay eggs, and in doing so effects the fertilization of the blossom. Were it necessary to produce the fertile seed of the fig, male trees, or caprifigs, would have to be planted close to the female fig-tree.

A PACIFIC-COAST HONEY EXHIBIT

BY W. L. COX

Here are some photographs of honey and bee exhibits at the Chehalis (Washington) county fair.

Figs. No. 1 and 2 show 1913 exhibits. The reader will observe Fig 1 bears a display card with the name J. D. Cox. Mr. Cox is my father, and owned the comb honey. One thousand sections were used. The extracted honey, beeswax, and bees were mine. The exhibit was 16 feet long.

Fig. 3 illustrates my home-made observation hive holding three eight-frame colonies. It has taken several blue ribbons.

In the 1913 program there were demonstrations each day, and short talks on bees, which proved very interesting and instructive. Several beekeepers present contributed to the program.

A part of the 1914 exhibit is shown in

Fig. 3, which was taken before he had the exhibit finished, though it conveys a good idea of what we had on exhibition. The

FIG. 2.—Bee products from W. L. Cox's apiary.

display was all mine except the little case of comb honey in the lower left corner. I had a corner space using 24 feet. The view shows the 16-ft. wall space containing the honey and wax. Portions of two observation hives are shown but not clearly. The end space not admitted to the photograph contained the extractor and other equipment used in the apiary.

The leading feature of this year's program was live-bee demonstrations by Master Roy Cox, aged eight years, who took the queen from a colony and carried her around for the crowd to see. He worked bareheaded and barehanded, with sleeves rolled to the elbows.

Porter, Wash.

FIG. 3.—Three eight-frame colonies are housed in this observation hive.

A Louisiana swamp is an unlimited source of nectar.

MAKING INCREASE IN A SOUTHERN SWAMP

BY J. D. BAILEY

My apiary is located five miles from New Orleans in the heart of a Louisiana swamp where an unlimited field of honey-plants abound. I have been keeping bees for a number of years as a diversion, but last year I moved them out to a friend's place and we have determined to increase our colonies and sell the honey. We started in the spring with fifteen colonies and have increased to forty-two, which we hope to have next spring.

The honey-house was put up by myself and a friend, both novices, at a cost of less than ten dollars, as all the material was second-hand. In the upper story our extractor, Peterson capping-melter, steam-

heated uncapping-knife, etc., are located. The honey runs direct from the extractor through a large pipe to the tank-room below, where it passes through an Alexander honey-strainer, and thence into a large tank with a capacity of five barrels. From there it is drawn off through a honey-gate direct into the containers.

Besides our bees we have an assortment of oranges, grapefruit, kumquats, loquat, dasheens, and last, but not least, a beautiful feijoa sellowiana.

Our bees are building up rapidly for winter on goldenrod, there being hundreds of acres within easy range.

New Orleans, La.

NO DANGER THAT WHITE CLOVER HAS WINTER-KILLED

BY ADAM LEISTER

[Mr. Leister is the farmer beekeeper whose advice on clover and other topics we have sought so often. Knowing that there has been little snow in most parts of the country this spring during the alternate freezing and thawing, we asked our friend what he thought about the clover prospect. His reassuring reply follows.—Ed.]

I have made careful observations on the effects of the freezing and thawing, and heaving of clover. I can say, without hesitation, that there has never been a season with so little heaving as the present one. I hear you asking, "How do you account for

this?" The observing eye has long discovered that a wet season is the most favorable condition for heaving. Since this has been an extremely dry spring, and since the season is so far advanced, the danger from heaving is entirely past.

The honey-house cost just \$10.

We may look forward to more than an average crop this year, and why? Those who have to do with seeding and harvesting the clover crop know well the injury from the clover-midge. This destructive enemy has almost entirely disappeared—at least in this locality, so far as my observation goes. I am not sure if this insect affects both red and white clover, but I notice that both white and red thrive well under similar con-

ditions. Another important factor in the conclusion is the very light rainfall for the spring months. To make up for this we are sure to get an abundance later. In summing up I will say that conditions are perfect, with about three-fourths of a stand of white clover, and a full stand of the red, with the promise of a good soaking at haying time.

Medina, Ohio.

HOW BEES IN ONTARIO HAVE WINTERED

BY MORLEY PETTIT

It is, of course, too early to give any definite report on how bees have wintered in Ontario; but letters are beginning to come in, and heavy loss is expected in all apiaries which were not carefully fed last fall. This is only what is to be feared, as the failure of the honey crop in 1914 left the hives weak in stores, and the failure to rear young brood properly the latter part of the season made most of the clusters small for going into winter quarters. To make matters worse, the outbreak of the European war caused a sharp rise in the price of sugar just before feeding time; and those who had not purchased sugar early even experienced difficulty in getting a supply at any price. Although the Dominion Government rendered considerable as-

sistance by corresponding with sugar-refiners, and urging them to make sure that beekeepers get their required supply, many beekeepers who were not specialists decided that they would let the bees take their chances, as they had not given any profit during the season.

The few reports which have been received indicate that clover may not be in the best of condition, but they also indicate a continued live interest in beekeeping, as renewals of memberships to the Beekeepers' Association are coming in quite freely, and numerous requests are being received for information as to where bees can be purchased.

Guelph, Canada.

A CHEAP AND EFFECTIVE GROOVED FEEDER

BY E. F. ATWATER

A year or two ago Mr. Jay Smith described his "Perfect feeder," built along the lines of the old Cary feeder. We usually have some colonies that use a disproportionate amount of stores, and we usually have quite a supply of feed, consisting of boiled honey from diseased colonies or other cull honey; and so to connect the two to the advantage of the needy colonies, and to our profit, we designed and built several hundred feeder-bottoms.

As we could not spend the time to build up feeders from countless little sticks, as

was done by Mr. Smith, and as no feeder holding less than a quart appeals to us as being very useful or practical, we had clear 2 x 6 lumber cut in suitable lengths for the ten-frame bottom-boards, and grooved as shown. The connecting holes between grooves are cut with a special tool.

We prefer to shove the hive forward on the bottom $1\frac{3}{4}$ inches, to expose the feeder, then lay a strip $\frac{3}{4} \times 1\frac{3}{4} \times 16$ across at the rear, for upon removing this strip the feed can be instantly poured in and the strip replaced. This can be done so quickly that no smoke is needed.

In early spring, if we find some colonies very short of stores we simply shove the hive forward, contract the entrance so only one or two bees can pass, fill the feeder with feed, and replace the strip.

Sometimes by the time we get over the yard the first colonies fed have licked up the quart of feed. Then we fill the feeders again (using a little smoke), often three times in an hour. That yard is safe for some time, and heavy colonies have not had their prospects injured by giving some of their honey to the light ones.

For regular stimulative feeding this feeder-bottom is the best. A thinner feed, and enough of it to do some good, can be given daily, or as often as desired.

In this connection we have found no considerable advantage in daily feeding except in queen-rearing, and believe that, even where regular feeding is found profitable, feeding a little more, every second or third day, will give about the same results as daily feeding.

But in any event it will pay to own a lot of these feeder-bottoms of ample capacity, as they are substantial and practical, and have stood the test of extensive use.

Meridian, Idaho.

The single clear 2 x 6 piece, carefully grooved, constitutes the feeder.

100 POUNDS PER COLONY AND NO SWARMS

BY S. M. CAMPBELL

Our bees are in fine condition, and we are putting on supers. We had a swarm to-day, March 19. So far we have had 20 inches of rain, and expect to get at least 75 pounds of honey to the colony, even if there is no more rain this season. The sages are in fine condition, and should yield a large surplus.

When I was in Texas I kept 145 colonies from swarming in the year 1910, and ob-

tained 100 pounds of extracted honey to the colony at the same time. I did not have a single swarm, and only six colonies built cells. My plan of procedure was as follows: As soon as the bees filled the outside combs in the brood-chamber I made the rounds of the apiary with a super of drawn combs. From each colony I took out the full combs of sealed honey from the outside, spread the brood-nest, and put these empty

Comb containing aster honey granulated so solid that the bees could not use it. Note the granules in the open cells at the left. These were almost like flint. The bees had gnawed the cappings from the other cells but had left the honey.

drawn combs in the middle. This gave the queen all the room she needed; and as fast as I got a super of full combs of honey I put it on top of the hive until I was ready to extract. The hives were tiered up three stories high (ten-frame hives), and at the end of the season they were full of three-banded Italian bees from the floor to the lid.

In these big mountains of California it pays to have apiaries located close together. The mountains are full of canyons with high ridges between, and the bees do not seem to fly over these ridges, nor care to go over them to the next canyon, perhaps only a mile away. For this reason smaller apiaries, say 100 colonies or so, are more logical about a mile apart. I have been in this country two years, and am satisfied that this is the best plan. In Texas or any level country, bees will fly a long distance in search of nectar, and in such localities one can keep much larger apiaries, but they

must be further apart. Small apiaries are nicer to work in, however, for one can get through the yard before the bees are hardly aware of it. This is quite a big item; and then, besides, when a poor year comes the small apiary will have enough stores to winter on, while the larger one is likely to need feeding.

Most of the writers tell us to have the colonies strong when the honey-flow comes on, but fail to tell the way to keep them strong. The best way to have a hive full of bees when the harvest comes is to have plenty of honey in the combs at the right time. Very few hives have too much honey, for the bees turn the honey into brood. This point can hardly be made too emphatic to the beginner, and even the veteran would do well to give the subject more thought—making sure that his colonies have plenty of stores.

Nordhoff, Cal.

ASTER HONEY AS A WINTER FOOD FOR BEES

BY JOHN H. LOVELL

After corresponding with beekeepers from Michigan to Georgia I am convinced that aster honey, if properly ripened and sealed,

can be safely used for wintering bees. Any honey, if unripe, would probably be open to objection. Mr. O. H. Townsend writes

from Michigan that he sells aster honey at the same price as that of the red raspberry, and that it has a fine flavor and a good body. He attributes its poor reputation for winter stores to its tendency to candy. Mr. Raleigh Thompson, of Underwood, Indiana, who has had great experience with aster honey, also reports that it crystallizes very quickly. It is so thick that it is difficult to extract. His bees winter finely on it with very little loss. The flowers are so abundant in his locality that the fields at times are as white as snow. Others in the central states have been equally successful. Mr. T. W. Livingstone, of Leslie, Georgia, says that it candies quickly if not sealed; but that when he lived at Dalton his bees depended on it for winter stores. Pure aster honey is nearly as white as that of white clover, but usually it is amber-hued, due to the presence of goldenrod honey or that of other autumn flowers. It is very sweet, with an agreeable flavor. Like goldenrod nectar, the nectar of the asters has at first a sour or rank odor which soon disappears.

Waldoboro, Maine.

[We have had good, bad, and indifferent reports of colonies wintered on aster honey. So far most of the reports have indicated trouble, as in the following:

Bees wintered badly. I had them all in the cellar, but they had dysentery from the aster honey. I have lost one-third of them—my heaviest loss in 30 years.
Solon, Ohio. H. C. LANE.

Our own bees having aster stores have shown more signs of dysentery than any colonies we ever wintered before. Colonies in the same cellar having stores of sugar syrup were clean and dry when set out.

One of the great drawbacks to aster honey, as mentioned by Mr. Lovell, is its tendency to granulate so quickly and so solidly. The illustration herewith shows the almost "gritty" appearance of the honey in the open cells. Many of the combs show the cappings gnawed away, and the honey in the cells so solid that the bees apparently were unable to use it.

Query.—Why should the solid aster honey in the cells be less available than the solid cakes of candy made from boiled syrup? See following article by Geo. H. Rea.—ED.]

STARVATION OF COLONIES ON CANDIED STORES

BY GEORGE H. REA

Reports of bad wintering are numerous this spring. The description of symptoms usually given indicates that the condition is largely due to aster honey gathered last fall for winter stores. If this honey has acted everywhere as it has in Medina, the wonder is that any bees with no other winter stores are alive.

About the middle of March the writer, with Mr. Arlie Pritchard, visited the Blakeslee yard of the A. I. Root Co. The covers of the great quadruple winter cases were lifted, and a peep taken at the clusters. The weather was too cold to do more than that, and, in fact, it has not been fit to permit manipulating colonies so far this spring (March 28).

Out of sixty colonies three were found dead. Sealed stores could be plainly seen along the top-bars of the frames in these colonies, while the bees were mostly on the hive-bottom. A small cluster in each case was still clinging to the combs. They had starved to death with plenty of stores in the hives. In fact, investigation showed that they were actually clustered on candied honey which they had uncapped but were evidently unable to consume. That seems

strange at first thought. Bees will eat hard candy, but this is the hardest candied honey that I have ever seen.

The illustration on preceding page shows this hard honey in the cells.

The wonder is that these bees were not all dead. Had it not been that at that time the weather warmed up enough that they could get out in small numbers and get water, they probably would have all died.

In previous years, when feeding hard candy I have noticed that the bees would get along very well as long as the weather was such that they could get out and gather water, but would sometimes die clustered right on the cake of candy during a spell of bad weather. Bees wintered in a moist cellar will use hard candy, while they will be unable to do so in a dry cellar. In the first case the necessary moisture is supplied from the atmosphere. The same might be true outdoors in wet weather—but not when it is cool and dry, as it has been this spring.

[As mentioned in the footnote to Mr. Lovell's article above, the reports from other sources regarding the aster honey are quite conflicting. It has become evident

from the reports of past years that in a locality where the bees can fly frequently, the aster honey does no great harm. Perhaps the bees in these flights bring in the amount of water necessary. However, bee

dysentery is never very bad where frequent flights are possible, and take it all in all, any bad condition brought about by poor stores would be relieved by frequent flights.
—[Ed.]

NOTES FROM GERMANY; WAX-RENDERING; BOILED HONEY

BY J. A. HEBERLE, B. S.

Highly interesting is what Editor Root says, page 921, 1914, about the wax-rendering station in Massachusetts. State Bee Inspector Hofmann-Muenchen has published in the *Muenchner Bztg.* an excellent article about wax-rendering in which he says that, years ago, oil was pressed from seeds with a loss of some ten per cent of oil.

For some time this method has been superseded by extracting with a solvent. The fluid solvent is condensed, and used again and again. This method needs very little care, and is, consequently, very economical. A gentleman interested in wax-rendering called the attention of Mr. Hofmann to the fact that wax could be extracted the same way as oil from seed, and more efficiently than by heat and pressure. Among the various solvents tried, benzine seems to be the most convenient.

An expert chemist has reported that wax extracted with benzine is chemically unaltered, but does lose its odor. This is considered of no importance, since by the process of bleaching the odor disappears also. [For foundation-making, wax with its natural odor will be preferred.—H.]

It has been suggested that wax be rendered as heretofore by heat and pressure, or by the solar extractor, and that only the residues from these methods be extracted by means of a solvent.

The process of extracting with a solvent is very efficient, all but about one-half of one per cent being recovered. This small remainder could be recovered, but it is not economical to do so.

A NEW BOOK ON BEES.

Notwithstanding Europe is under the reign of Mars, and "grim-visaged war shakes its gory head," there appeared the first month of this year a new scientific work about bees. The title is "Leben und Wesen der Bienen"—Life and Nature of the Bees, by Prof. Dr. H. v. Buttel-Reepen, published by Vieweg & Sohn, Braunschweig, Germany, price \$2.00. The author is well known to the readers of GLEANINGS.

This book differs from the many good text-books we have. It is designed to supplement them. It is strictly scientific and impartial. Anybody who wants to study the bees—who is interested in knowing what amount of research and study the bees have been the subject of on the part of men of science, should get this book. Some 23 pages are needed to enumerate the titles of books and journals referred to in this book. In a short notice I cannot give the reader a fair idea of the contents. Especially interesting to me is the tenth chapter, "The senses of the honeybee." It is subdivided into five divisions. I. The sense of location; II. The sense of color and form; III. The sense of sight; IV. The sense of smell; V. The sense of hearing and communication.

About the sense of hearing, I have seen less in current literature than about the other senses; so I give a few items from it. Considerable study and investigation by eminent men on the subject, "Can bees hear?" has not entirely solved the question. Some say the bee has no sense of hearing. It perceives only vibrations. Others say the bee does hear. Among these is the author of the book, but he gives dissenting opinions and references. He gives a very convincing argument when he says that it seems logical to suppose that creatures which can produce a variety of sounds which unfailingly express certain conditions, that such creatures also have the ability to hear these sounds. The beekeepers know of various tones the bees can make—for instance, when a swarm is in the air; when a colony first notices the loss of its queen; when the bees have a good honey-flow; the gay hum when a swarm enters its new home; the war cry of the excited angry bee when attacking. The call of the queen first hatched, and the answer of one or more in the cells, etc. It certainly does seem reasonable to suppose that the bees hear these sounds—or feel them.

The scientist Lubbock has played the

violin for the bees; he blew the flute, whistled, shouted, but they took no notice of it. Others have repeated this experiment with the same result.

The scientist Ed. Hopper, an authority on the bumble-bee, holds that they are endowed with a sense of hearing, while Sladen and Wlad. Wagner hold the opposite view. Ed. Hopper tried the following experiment with *Vespa media*, De Geer, to see whether or not they would react on sounds the human ear perceives. He hid himself in the bushes, and with a long cane he excited the above-named species by punching and shaking the bush on which their nest hung, at the same time whistling loudly. They came out of the nest pell-mell to attack the disturber. Later he needed only to whistle to bring them out, full of anger, searching for the offender they had heard but could not see.

There is still some uncertainty how external impressions are made conscious to the bees. We beekeepers cannot but be thankful to the men of science who have already revealed many of the wonders of the make-up of the little honeybee. Just think! there are 31,000 minute membrane plates with nerve fibers attached to them, called poreplates, although they have no pores at all, found in the two antennæ of the drone. The thickness of these poreplates is 0.002 to 0.004 of a millimeter, or 0.00008th to 0.00016th of one inch. Their use is uncertain. They are considered too thick to transmit odor, as gases would not diffuse

rapidly enough through them. It is curious that the queen and workers have only about 4000 in both antennæ, but a little larger in size. The author of the book thinks they may help the drones to find the queen at the mating flight, since that is the only service the drones seem to render the colony.

McIndoo's work on the sense of smell, familiar to American beekeepers, is also considered. Sixty illustrations help very much to interpret the weighty contents of the book.

BOILED HONEY NOT SUITABLE WINTER STORE.

Regarding the editorial article, page 4, in GLEANINGS for January 1, I should like to say that I have often heard the opinion expressed that honey with a comparatively small amount of water gives dysentery. A colony suffering from the want of water becomes uneasy, and dysentery results. Boiling changes honey considerably. The loss of water, and the change in the hygroscopic property, are most important for its quality as winter food.

If honey for winter feeding has to be boiled I would suggest that a liberal amount of water be added, and that the honey be stirred so that it may not get on the walls of the vessel too hot while part of it is barely warm. It is usually recommended to dilute honey with water for feeding purposes, the quantity varying up to equal volumes. [We have always diluted the boiled honey that we use for feeding.—Ed.]

Kempton, Bavaria, Germany.

THE SECTIONAL HIVE

BY F. GREINER

In an address entitled "Practical Side of Apiculture," delivered before the Ontario County (N. Y.) Beekeepers' Society last January by Mr. S. D. House, Camillus, N. Y., two sentences struck me as of importance. They were as follows: "We handle hives rather than frames;" and "our wide-frame supers assist us in handling the finished product rapidly." Great masters may make mistakes, to be sure. I am reminded what Dr. Dzierzon once said about the labor-saving mania of the American beekeeper. He said in substance: "As though success depended on the ease or rapidity with which hives may be manipulated, can we not employ women and children (in other words, cheap labor) to do this work?" This was many years ago. In the light of our experience of the past years, who of us on this side of the big water endorses this theory of Dr. Dzierzon?

So, I say, possibly Mr. House is wrong. We hear very little said about the sectional or divisible hive, and still less about the wide-frame super. The different photographs of apiaries appearing in every issue of our American bee journals do not indicate that sectional hives are very popular. I have heard extensive and successful beekeepers say that they had a lot of the reversible sectional Heddon hives on the rub-bish-pile, and that they could be had for the asking. Notwithstanding all this, one must learn to use a tool right. The best kind of razor, no matter how sharp it may be, cannot be used successfully to cut brush; and the best brush-hook is ill fitted to cut a man's beard if the bristles are never so thick and heavy. The sharpening of a razor is one thing, and that of a brush-hook, another. The sectional hive is not to be used in the same manner as the standard L. hive is

used. The attempt will result in a miserable failure.

Listen to what Mr. House said about the use of his hive before the convention in Canandaigua:

"When our bees are wintered we do not disturb them till fruit-bloom, when every good colony is given a sectional hive-body full of combs. (The supposition is, every colony has been wintered on two sections, equaling all together eight or nine L. frames.) This hive-body of combs is given in between the two already occupied. The bees will immediately take possession of the combs, and they will be quickly filled with brood. We keep an eye out for the clover-

chamber to remain on the stand which appears to have the most sealed brood. The other two (from each hive) are placed on a new stand with entrance almost entirely closed for the time, or even closed entirely for a few days. The few matured bees left in the combs, and the newly hatching bees, will soon be able to take care of the young brood, although some of the youngest may perish, which is of little account. When increase is not desired the brood-chambers so removed full of brood can be utilized for strengthening weak colonies; or if none are on hand they may be allowed to stand until they have a young laying queen from a queen-cell furnished them. The colonies may

Quinby's original metal-can honey-extractor. See letter from L. C. Root, p. 260, last issue.

Interior of Quinby's extractor. The gearing was made up from parts of an old fanning-mill.

bloom; and when the bees bring in honey at the rate of one pound per day from this source we take two sections of brood and honey away from each colony and give them two comb-honey supers instead. I don't want any sort of bait comb in my supers, as this would only result in pollen-loaded sections. With full sheets of comb foundation pollen will not get into the sections, and an excluder will not be needed. To free the little brood-chambers, which we wish to take away, from bees, we do not brush a bee from a comb but drive them either up or down with a few puffs of smoke. It is done quickly, and we select that brood-

then be united again, removing the old queen.

"With a good honey-flow the colony with its reduced brood-nest will need looking after, for the supers will be filled as by magic. The empty super should always be added next to the brood. The sealing of the honey must take place as remote from the brood as is practical. The cleanest honey, none travel-stained, will result in this way. To provide ample ventilation the hives run for comb honey should be placed on four blocks. This will usually prevent the swarming fever from breaking out. If it should come to the worst, a hive-chamber

filled with comb foundation is given, but this only when queen-cells are being built.

"In uniting the colonies at the end of the honey season the queen in the lower brood-nest is usually killed by the bees. In case we did not take time to hunt out the old queens we proceed in this fashion:

"All honey is removed as soon as finished. By the use of the sectional hive we have no dummies under any part of our supers. Over dummies bees never do the work as when all sections are in close touch with the brood-nest."

I believe, in the above, I have covered about all Mr. House told the convention, and I want to say that I have for some six

years or more handled a portion of my yards along this line. At times I have used a modification of the plan outlined, following Mr. Taylor, of Colorado, and Mr. Hand, of Ohio; and I can say that I am well pleased with this style of hive and its workings.

As to the wide-frame super, I can only agree with Mr. House, having used this style extensively for more than 35 years, and am perfectly satisfied with it, using now no other. It protects the honey-boxes on all sides, thus giving us the cleanest honey with the minimum of labor.

Naples, N. Y.

BEES AND FRUIT-GROWING

BY S. H. BURTON

That bees are an important factor in fruit production has long been proven; and the time is coming when the orchardist will consider a few colonies of bees in the orchard as much a necessity as a sprayer.

With increased spraying we are destroying the beneficial or pollen-distributing insects as well as the injurious ones; and to offset this loss more bees must be kept.

Observations taken at different times in my own orchards show that weather conditions, governing the flight of bees during the time of blooming, have more to do with the setting of a good crop of fruit than any other one factor in fruit production. Here is some very striking proof:

In a peach orchard of mixed varieties are located several colonies of bees; and during one particular season at blooming time the weather was very cool and cloudy, with a cold east wind. Several cold cloudy days followed with drizzling rain, and the bees did not visit the blossoms except at rare intervals, when the sun would warm things up for a couple of hours. The row of trees directly in front of the hives bore an enormous crop, while the trees on the distant side of the orchard produced scarcely a dozen peaches each.

DOES SPRAYING KILL THE BEES?

Under certain conditions the use of arsenicals is very destructive to the bee, and orchardists who have given the matter careful study will adopt means to prevent the wholesale destruction of these most valuable insects. Spraying while in full bloom is not considered good orchard practice. The poisonous spray falling on the sensitive stigma of the flower injures it by burning, and you not only kill the bees but defeat the very

purpose which is sought—that of a good set of fruit. Only a few varieties of apples, notably the Roman Beauty, close the calyx cup as soon as the petals fall, and it is well to begin spraying this apple as soon as possible after blossoming.

Most orchardists begin applying the codling-moth spray when about three-fourths of the bloom has dropped. By this time the flowers have ceased to yield nectar, and are no longer visited by the bees. The stigma in the flower-cup has dried up, and no harm results from the spray falling on the blossom.

The greatest danger of poisoning the bees lies in the fact that most orchardists use some variety of clover, either singly or in mixture, as a cover crop; and about the time for the third summer spray this clover is in full bloom. At this spraying, arsenate of lead is used to control the second brood of codling moth, lesser apple-worm, and other leaf eating and chewing insects. The poisonous spray falls on the cover crop, is blown across the middles between the trees, and every orchardist who has done much spraying will admit that as much spray material falls or is blown to the ground as sticks on the trees, and herein is where the trouble lies.

RED CLOVER UNDER TREES DWARFED.

Not much importance is attached to red or crimson clover as a honey-plant, and bees do not usually visit the blossoms; but the moisture taken up by the trees and the shade tends to dwarf the blossoms, shortening the length of the corolla till the bee is able to sip the poisonous nectar from the flower-cup. To obviate this trouble the orchardist should mow the cover crop just

previous to applying this spray. Several advantages are to be gained in this. He saves the bees, stops the loss of moisture that is being pumped out of the soil by the clover, and provides a mulch over the or-

chard that is needed at the right time. This mown clover can later be disked into the soil, which is a better method than turning it under green, preventing acidity of the soil.

Washington, Ind.

THE EIGHT AND TEN FRAME HIVES, AND HOW TO USE THEM

BY J. W. SOUTHWOOD

A few years ago it was thought that the eight-frame hive for comb honey and the ten-frame for extracted honey were the proper sizes for best results. But at present the minds of some, at least, are for a larger hive, especially for the production of comb honey. The claim is that a ten-frame hive will give better results than an eight-frame. While this is true with some colonies, and may be true with all colonies in some localities, the fact that many have the eight-frame hive, and, considering the expense of disposing of them and getting the ten-frame, it may deter some from making the change.

To obviate this some have advised placing another hive-body on top, that thereby the colony can build up by the use of the eight-frame hive. It is undeniably true that there are queens which, for best results, require more comb space for egg-laying and brood-production than is contained in the eight-frame hive. It may be the proper thing to do with some colonies, and it may be with all colonies in some localities, to give the added hive-body in the spring, at the proper time when the colony is building up; but in far too many cases this added room of eight frames for the production of comb honey may be too much. It would be quite likely that, before the added hive is filled, the honey-flow is on and the first super of sections is given, and, instead of the honey being all stored in the sections where it is desired, a part of it is deposited in this unfilled hive-body.

As a compromise, last season I prepared some ten-frame hive-bodies, and when a colony built up until it was strong I made an examination; and when I found that the queen was needing more comb space for egg-laying I lifted out the frames and placed them in a ten-frame hive in the same position they held in the hive from which they were taken; and on each side I placed another comb. It so happened that I had two colonies that were queenless and contained laying workers with but few old bees and but little honey, and so I used these combs. When the last two combs were

taken out, what few bees were on them were shaken in front of the colony to which I gave the combs. I had intended to use frames with full sheets of comb foundation; but as it so happened that I had the combs, I used them instead.

When the flow came I put the eight-frame supers of sections on these ten-frame hives, placing a strip of lath at each side of the super to cover the space left open by the super being narrower than the hive. When these colonies swarmed they were hived in eight-frame hives on the old stand, and the super, or supers of sections, were taken from these ten-frame hives and placed at once on the new colony with a queen-excluder beneath.

This method gave the queen the necessary room, and thus gave more populous colonies than there would have been if left in the eight-frame hives. It retarded swarming; so when they did swarm, the swarms were larger than they would have been if they had been left in the eight-frame hives. Some colonies that were left in the eight-frame hives gave more section honey, perhaps, than they would have given if they had been moved into ten-frame hives, as the queen had all the space that she needed for brood-rearing, and what honey would have been placed in the two side combs went into the sections. The method gave such satisfactory results that I am intending to try it again the coming season. Whether these two combs should always be placed at the sides, or whether one should be placed at the side where the comb containing more brood and eggs than the other is located, and the other somewhere in between some of the other combs, may be a question. Not only hive conditions but weather conditions should be considered. It might be safer for the beginner to put the combs at the sides.

With this method the eight-frame hives need not be discarded, and yet get the benefit derived by the use of the ten-frame hive. Yes, and even better, as the eight-frame hive in some instances will give better results than the ten-frame, as I have already stated.

Huntington, Ind.

HONEY VS. SUGAR SYRUP

Does Sugar Contain all the Essentials for Rearing Brood?

BY J. E. CRANE

Dr. Miller drops a Straw on page 218 that appears to hold a considerable grain of value, and is well worth our consideration. He has gleaned from back numbers of German bee-journals that there is a belief in Germany that sugar is not as good for building up colonies in spring as honey, as honey contains several substances that are lacking in sugar that are essential in repairing waste in mature bees, and the rearing of brood. He mentions "invert sugar, pollen, ethereal oil, tannin, malate, tartrate, oxalate, and nitrate of potassa, different phosphates, manganese, natron, silica, sulphur, lime, iron," as necessary in the make-up of a bee's body. So it comes to pass that, where sugar is used in spring, bees are slow to build up until they can get honey from natural sources. In this country it is generally thought that sugar is just as good as honey. "Are the Germans right, or are we?" he asks. In common with others of America I have thought it made little difference whether the bees had honey or sugar in the spring, provided they had enough of it; but my experience last season set me to thinking I may be wrong.

This was my experience: Having had two poor seasons in succession I was a little short of a full stock of bees for winter, but had several hundred dry combs. Why not, after the clover went by and all hopes of surplus had past, divide strong colonies, using up my surplus combs, giving young queens and feeding thin sugar syrup to get a good supply of brood, and in October feed sugar syrup for winter? We made some seventy-five new colonies from twice as many old colonies. All seemed to work out about as we expected, except that we failed to get our hives filled with as much new brood in August and September as we had hoped, although they were fed with a thin sugar syrup, week after week with great regularity. There was some brood, but not enough to make strong colonies for winter. Was the cause sugar syrup instead of honey? It certainly looks that way.

On page 228 and 229 Mr. George Shiber tells how he prefers sugar syrup for wintering bees; but for building up in spring he says nothing equals "sealed combs of natural stores." Some years ago it was told somewhere that raw sugar was much better than refined sugar for stimulating bees to rear brood; and we find that such sugar

contains some five or more per cent of organic and inorganic compounds, while refined sugar is almost perfectly free of them. We all know that potash, phosphorus, lime, etc., are essential in building up healthy animal bodies, and it is to be presumed that bees are no exception to the rule. I reasoned that, as there was an abundance of pollen to be had during August and September, all that was needed was to feed regularly thin sugar syrup to imitate the nectar of the flowers. I could very cheaply build up a large stock late in the season when bees could do little else. I did not have the advantage of buckwheat or goldenrod, nor even swamps to any extent. Of the seventy-five new colonies, I believe scarcely any of them could be called strong, as they would if a good flow of honey had been coming during the month of August from buckwheat. The experiment was on a sufficiently large scale to be of some value. It seems to me now, as I look the experiment all over, that neither pollen nor syrup from refined sugar contains all that is needed for rearing brood rapidly. The pollen doubtless contains these elements to some extent, but not enough for the best results. I wonder if others have had experience along this line.

Middlebury, Vt.

A MEMORY

A Friend's Reminiscence Retold

BY GRACE ALLEN

The path to Mammy's kitchen winds
Amid the garden tangle;
And in between the hollyhocks,
Among old-fashioned four-o'clocks
And beds of marigold and phlox,
Stand hives at every angle.

The barefoot children leap and play
Like wind-tossed morning glories;
Then "Ouch! I'm stung!" and swift they get
Some grass or leaves or mignonette
And touch the place and so forget!
Such faith in Mammy's stories!

"Stung, Honey-chile?" black Mammy'd say,
"Well, don' you fuss an' tend it;
De Debbil's mebbe in de stings,
But God Hisself is in de wings,
An' in de grass an' blossom things—
A bit o' God'll mend it!"

Heads of Grain from Different Fields

Beeman's Laws

BY IRMA TRUE SOPER

The poets sing of the gentle spring,

The drowsy hum of bees;

"The world's in tune" the poets croon,

"With blossoms on the trees."

But the beeman knows, if his business goes,

He'll take the yoke and work;

He can't sit down nor hang "round town"—

He mustn't be a shirk.

It's the man who drives the nails in hives

And brood-frames all day long

Who doesn't swear nor tear his hair

When an orn'y nail goes wrong,

But yanks it out for another bout,

Then drives it straight and true,

Till the hives look trim and square to him—

His skies are brightly blue.

An aching back we will not lack

To speed him on his way;

While the sections fill the supers till

They all are stored away.

It's the man who'll smile serene the while

A dozen stings he's found,

When he takes the bug from their cellar snug

And sets them on the ground.

He'll keep his grip till he makes the trip,

Nor pause to pull out strings;

By beedom's laws he must not pause,

Nor mind such little things.

So the poets sing of the gentle spring;

But there's work that must be done;

The beeman knows if his business goes

He'll mix his work with fun.

How Swarm Prevention may be Overdone

I am at home about two days in seven, and depend on my wife and neighbors to hive the bees when they are swarming. I was at home when they swarmed once. They swarmed every week the first two seasons, and all absconded. By reading books and journals I discovered that, by clipping the queen's wing and destroying queen-cells, I could stop the swarming. This was in 1913, the best season we ever had for honey—so say the writers. I had three very strong colonies which hung out in front of the hive. I raised the hives up on four bricks each; but still they did but very little work. I put a small super on each of the hives. They did not pull all the starters nor cap any of the combs. What can I do to make the bees work when the queen-cells are cut out every seven days, as in the above case? They did not swarm in 1913. My neighbors who let their bees swarm received 152 lbs. of comb honey per stand the same year.

Crestline, O.

H. M. BROWN.

[Dr. Miller, to whom the above was directed, replies:]

You operated on the theory that, if you clipped the queen's wing and cut out all queen-cells every seven days, your bees would not swarm. The result was that, while your neighbors got 152 lbs. per colony, you didn't get a finished section. Something wrong somewhere. Let's examine your theory. If the queen's wing is clipped she will not go off with a swarm, because she cannot. To be sure, the swarm will issue just the same as if the queen could fly; but when the swarm finds it is queenless it will return to the hive unless, as sometimes happens, it joins another swarm having a queen with whole

wings. But that doesn't often happen, especially in a small apiary. Yet if the colony is left to itself a virgin will issue in about eight days, and with it off goes the swarm. You block that game, however, by cutting out queen-cells each week. In that case no swarm will go off with a virgin. How can it when there is no virgin for it to go off with?

Your theory seems to be all right, so far as it goes. It seems to be a case in which "a little learning is a dangerous thing," for your learning brought you out away behind your neighbors who were without that learning. Let's get after the rest of the "learning." First, let us inquire what likely happened with a colony treated as you treated yours. The swarm issued with the clipped queen, and returned. But there's no certainty that she returned. She may have been lost. If she returned, the swarm would keep issuing until she was lost, or until the bees, dissatisfied with her, balled and killed her. In any case, you may count on it that, when a colony with a clipped queen swarms and is left to itself, the clipped queen will disappear within a day or ten days. Even if the queen should be left in the hive as long as ten days, there will be practically no eggs laid in that time. Also, egg-laying had dwindled and practically ceased some time before the swarm issued. So within less than three weeks all recruiting from hatching young bees would cease; and with the bees dying off at the rate of a thousand, two thousand, or more a day, and a colony discouraged because their owner had destroyed all chances of another queen, it is easy to see that the prospect for a big harvest would go glimmering.

Even so, it seems that in so good a year the dwindling force of bees should have done more than they did at gathering surplus. In the first place, let it be considered that, while no eggs were being laid, each day young bees were hatching, leaving empty cells to be filled with honey, and in less than three weeks every cell in the brood-chamber except those filled with pollen would be at the disposal of the bees for storing surplus. The bees prefer the brood-chamber to any spare room above; and so, although a considerable surplus may have been stored, it was all stored in the brood-chamber.

There may, however, have been a change made in the program laid down that would have accounted for a much smaller amount of honey. It is not an easy thing to be sure that you have cut out all queen-cells. I've often seen them so hidden that the most experienced might be excused for missing them. You may have missed one. Then one fine day while you were fondly trusting that no swarm could issue, and so no watch was kept, out came a rousing swarm with a virgin and sailed away in the ethereal blue. And if you had been expecting any thing of the kind you might probably have noticed that all at once the bees ceased to hang out.

Well, you're not likely to be caught that way again; for you have learned that, while clipping queens and destroying queen-cells stops swarming, it also stops some other things, and there is something further for you to do. Understanding the difficulty, you may be trusted to study out what plan will suit you best to proceed; but it may do no harm for me to suggest one way.

If you want increase, you may shake a swarm as soon as you find cells well advanced; for I take it that your business allows you to see the bees almost daily, but not at the time of day for swarming.

If you want no increase, you may let matters proceed until cells are sealed and the queen is gone, or you may kill her. When sure the old queen is out of the way, kill every cell but one, and there you are with a colony having shortly a young queen,

and in the very best humor for the most vigorous storing. If you care to take a little more trouble, a little variation may be better. When the old queen is out of the way, leave the cells undisturbed. In less than a week after the first cell is sealed, the young queen will emerge. About this time go every evening and lay your ear against the side of the hive. As soon as the first virgin has emerged, you will hear her piping. No danger but you'll recognize it the first time you hear it—a shrill note long drawn out, followed by several other notes in rapid succession, each one shorter than its predecessor. You will hear the replies of her young sisters as they quahk in their cells. If still light enough you may act at once. If not, go next morning and kill all the cells in the hive. That's all; the bees will do the rest, for you have left the piping queen, which is now in full possession. This is better than destroying all cells but one, for in that case you may leave a cell with a poor queen, or even with a dead larva in it.

Marengo, Ill.

C. C. MILLER..

When is a Pear Not a Pear?

Dr. Miller, on page 177, refers to a statement made by some one that the alligator pear is worthless if allowed to ripen on the tree, and says the same rule holds good with nearly all pears. It does not seem to be generally known that the alligator pear, or avocado, is not a pear at all, nor any relation thereto. The pears belong to the apple family, the avocado to the laurel family, which includes sassafras and camphor trees, and several varieties of bay trees. The botanical name is *Persea Persea*; but lately the government botanists at Washington say *Persea americana* is the correct term.

I have never found that it made a particle of difference whether the avocado pears ripened on the trees or not. They should be eaten when mellow, not when the least bit hard, and not when overripe or mushy. They usually drop from the tree a few days before they are just right to eat. Of course, to ship them any distance they would have to be picked greener.

Double Up the Eight-frame Hive

What shall I do with my two-story eight-frame hives of bees in the spring when running for comb honey? Let me explain: In the spring, soon after apple-bloom, I find my best colonies are becoming crowded. I then take brood from them and give to the weaker colonies as fast as I think they can cover and take care of the brood; but even then I had last season about twelve colonies that I apparently could not keep down. So I gave them an extra hive body and set of combs which they filled very quickly.

Now, I don't want to divide, and I have tried placing a super on top, when sometimes I get a small amount of comb built, but nothing like what I get with my strong one-story colonies. If I place a super between the two bodies, the sections that are finished are very dirty.

Has it been found to be of any particular advantage to go to the extra work of placing a small strip of foundation in the bottom of sections when the top strip or piece comes within about $\frac{1}{4}$ inch of the bottom?

Elkhorn, Wis.

W. L. SHERMAN.

[Where the eight-frame hive is used, the plan of making them two stories during the early bloom previous to the main flow is a good one. If a queen-excluder is not used it gives the queen room to lay to her utmost capacity, and will produce tremendous colonies of bees. This is what you want for successful comb-honey production.]

Where the clover-flow comes on, remove the upper story and take from the lower hive the outside comb, which, when a two-story hive is used, will seldom be found containing brood, and take from the upper story sufficient combs of brood to fill the lower one clear full. It will now contain nothing but frames full of brood and perhaps a little honey. The queen should also be put into the lower hive. Then put on your supers. If one super will not hold all of the bees, then put on two or three. If the weather is warm, block the hive up from the bottom-board so as to give abundant ventilation below; and if weather conditions are right and the bloom in abundance you will be surprised at the amount of honey that will be stored. The honey from the remaining combs can be extracted and sold, or fed back.

By this system your hive will be crowded with bees and brood, and they will probably swarm; and yet colonies that are in such condition that they will go into the supers with a rush, especially if the honey-flow is heavy, sometimes will not swarm as readily as others that are not quite so strong. In case there is more brood than will go into one hive, about the only thing that you can do with it is to give it to other colonies, if you have such, that will take it, or make increase. It is practically impossible to produce comb honey on top of a two-story hive. This you have found by experience.

Your experience with placing sections between two hive-bodies containing brood is in keeping with that of other beekeepers who have tried that plan. It is a good place to get the foundation drawn out and storing started; but after that they should be removed. The cappings will always be discolored with material taken from the brood-combs.

It is a decided advantage to use a bottom starter. You can always be sure of the combs being securely fastened to the bottom of the section, which is not always the case where only a full sheet is used that comes within a quarter or half an inch of the bottom.—G. H. R.]

Making Division-board Feeders of Metal

My Doolittle feeders require repairing every year. Since the feeders are made of wood, they shrink, which, of course, causes a leak. Feeder testing and repairing has become quite an annual affair. I have been thinking that the feeders should be constructed of stout galvanized iron, then painted, and, while the paint is wet, apply very fine sawdust. The sawdust would take away the cold touch of the iron, for which it is known the bees have a strong dislike; and, from the standpoint of the bees, would be the same as a wooden feeder, the coarse sawdust also giving the bees a good footing when taking the syrup.

From the standpoint of the beekeepers there would not be any loss of time in testing and repairing, and, above all, there would not be the annoyance that is caused by a leaky feeder.

St. Albans, New Zealand. W. A. SILLFANT.

But is Paralysis Caused by Pollen Constipation?

M. Y. Calcutt says, page 26, Jan. 1, that bee paralysis is caused by the bees becoming pollen-clogged. That being the case I can see where the cascaret would relieve them. But what I can't get through my head is this: If the bees are pollen-clogged, as he says they are, and giving them a cascaret will effect a cure, then how can it effect a cure to discontinue brood-rearing when they are storing honey in the supers?

Why would they not be pollen-clogged just the same after brood-rearing has been discontinued, and they are storing honey in the supers as before?

OUR HOMES

Editor

That we also may be like all the nations.—I. SAMUEL 8:20.

Thou shalt not follow a multitude to do evil.—EX. 23:2.

Thou shalt not covet.—EX. 20:17.

Thou shalt love thy neighbor as thyself.

—LUKE 10:27.

In our recent Sunday-school lessons we have been considering the people who wanted a king, and they petitioned the prophet Samuel until he, by Jehovah's direction, consented to give them a king, but at the same time made vigorous protest by telling them how it would turn out. A startling truth confronts us here. God, at least sometimes, grants importunate prayers by letting us have things not best for us. We should always preface such prayers by something like this: "O Lord, grant this petition, only if thou seest it will be best for us and humanity at large."

Again, the reason the people gave Samuel for wanting a king was because it was "the fashion." Because other nations, perhaps heathen nations, had kings, *they* wanted a king. They wanted to be like "other folks." This is all very well if the "other folks" are in the "straight and narrow path." Even at this present day it is sometimes a very *easy* thing to "follow a multitude to do evil."

Before taking up our two other texts I want to tell you a little story of my early boyhood. It happened so long ago I shall have to "fill in" a little; but it was substantially as follows:

Between 60 and 65 years ago *marbles*, instead of baseball, was the fashionable game. As soon as it was warm enough in the spring, all the boys (and some of the girls too) were playing marbles. I soon became tolerably expert, when some boy came among us and taught us how to make the game *more* interesting by playing for "keeps." To my great dismay, however, my good mother forbade my having any thing to do with that kind of game. It soon got such a run that the boys could hardly be kept in school, and all home duties and "chores" were neglected. It soon got out that *my* mother forbade *me* to do more than look on. Have you ever been there, dear reader? Can you still remember the looks of the "bully" of the crowd as he stands before you and says:

"Sonny, is it true that your 'ma' won't let you play? Better run right home; you might get hurt, or get in with 'bad boys.'"

And can you remember how the crowd hooted and "hollered"?

I said to mother, "Why, mother, every

single boy in school plays for keeps, and their mothers don't say a thing about it. *Why* can't I play, and be like the rest?"

After much like importuning she finally said:

"All right, Amos, you go and play, and see if you will be any happier; but please come and tell mother how it turns out."

I soon found two boys who were willing to play, and one of them was my best and most intimate friend. I very soon had all the marbles from both boys, and went home to show mother how much I had "gained" so quickly. Her next question was:

"What did Ariel say, when you won all his marbles?"

I hung my head; but when pressed I replied:

"Why, he got mad first, and said I cheated; and when I got his last marble he cried."

She put her loving arm around me and said, in a very low but kindly voice:

"My boy, don't you think you will be far happier if you run right over now and give the boys their marbles back again? You didn't *buy* them; you didn't give them *any* equivalent. You have all this bagful that you don't need and don't want, and they have no marbles at all."

I think I must have been barefooted and bareheaded as I scampered to both boys' homes and saw them both look, not only happy but friendly, and I made just restitution. May God be praised for that wise mother, and for the fact that that early lesson has lasted me sixty years or more. I do not think I have ever since taken any thing in any game of chance, and I believe I can say almost as much for our five children and ten grandchildren. Mother cured *me* as God tried to cure the uneasy and rebellious people who wanted a king because "other people" had kings.

While the incident above cured me from *gambling* it didn't seem to cure me or keep me from the craze for "gift enterprises." When I was about 25, and kept a jewelry store, a firm in Buffalo, N. Y., with whom I had dealt, sent me a box containing 100 packages to be sold at 25 cts. each. Each little box contained four papers of needles and a prize or gift. These gifts were valued at from 10 cts. to a \$10 watch. Very soon the store was crowded. It was like a lot of bees around a piece of honeycomb. The excitement was soon such that poor people bought needles enough to last them

forty years or more. The first box went so quickly I wired for a second. I don't recall where my good mother (or wife?) was just then; but here is lesson No. 2 that God sent me:

A washwoman whom I knew came into the crowd with about a dozen broken packages and a lot of jewelry. I distinctly remember among the lot a gold(?) locket and neck-chain said to be worth *ten dollars*. She broke right in through the crowd and said something like this:

"Mr. Root, you probably know that my husband and I have hard work to get along and care for ourselves. Well, we had just scraped up money enough to get a sack of flour, and I trusted the poor old man to go up town and get it. This crowd you see here persuaded him, if he bought your needles, he *might* get a gold watch that he could swap for several sacks of flour. Now, here is what he brought home instead of the flour. What does the like of us want with these trinkets? If they are of any value to anybody, you know how much and what to do with them. Will you kindly excuse my poor old man and take these and give me the money to get the flour?"

I was not a professing Christian then;

but I shut up the box and told the firm that sent it they could allow me what they chose or nothing, and from that time to this I have tried to steer clear of "prizes."

Just about a year ago a young beekeeper paid us a visit. Between here and town some lots were sold at an auction. A little girl gave out cards. Our young friend took one of the cards from the child, and it happened to be worth \$20 on the purchase of a lot. He didn't want any lot; but a man who expected to buy one gave him, I think, \$15.00 for it. So he made a visit to A. I. Root and gathered in quite a few "shekels" on the way.

If I am rightly informed, something similar is going on most of the time down here in Florida, and perhaps in many other places where there is excitement about real estate. I feel sad when I see it or hear of it, and sadder still when I meet so many who seem to think no harm may come from that way of doing business. If nobody wanted (or coveted) anything without rendering a fair equivalent, what a happy world this would be! and if everybody really loved his neighbor as himself, God's kingdom *would* come, and his will *would* be done on earth as it is in heaven.

HIGH-PRESSURE GARDENING

HOW TO MAKE "THINGS" GROW.

I have been expecting some of you would complain because I, as I grow older, get to telling the same thing "over and over." I have heard no such complaint as yet; and when it comes I am going to "come back at you" with the declaration that there are things that *should* be told "over and over," and what I am going to talk about is *one* of the things.

Perhaps thirty years ago it was, when one of my hobbies was the growing of vegetable-plants for the local trade around Medina. The plants were grown in shallow boxes about a yard long and 16 inches wide, and about 3 inches deep. We first put in a layer of old well-rotted stable manure, and on this some rich sifted garden soil; and when we were short of plants, and it was desirable to rush them along, we sifted in a little guano. Well, when the weather became real warm, say in May, we found the flea-beetle was getting bad on our young cabbage-plants; and reading in a paper that slaked lime, or lime water, would head them off, I told the boys to sift some lime into the soil before they sowed the seeds, and then forgot all about it. In

a day or two my attention was called to a box of plants of such luxuriance and dark rich color that I uttered an exclamation of surprise. The first seed-leaves of the cabbage were larger than any thing I had ever seen; and when I began making inquiry I was told it was the effect of both lime and guano. Then I began to explain to the interested crowd that the lime had probably liberated the ammonia in the guano at just the time the sprouting seeds needed it, when one of them exclaimed:

"Ammonia? I should say so! When I sprinkled the box with warm water, as you told us to do, after sowing the seeds, it smelled like a bottle of hartshorn or smelling-salts."

After we had tested the matter so we were satisfied we could get the same result *every time*, I said to the boys something like this:

"Boys, if some one had come along here and showed me a box of plants like these, and had offered to sell me the secret for a *hundred dollars*, I think I should have paid it at once."

Well, we grew plants in that way for several years; and if I remember we gave

it up only when guano seemed to be out of the market. Yes, good poultry manure will give a similar result, but not so marked. You may recall that when Prof. Thorne, of our Ohio Experiment Station, said so much about lime for sweet clover and other legumes I recalled this incident.

Well, since our supply of potash has been recently cut off (here in Florida, especially), attention has been called to guano; and remembering my experience of years ago I sent to Crenshaw Bros. Seed Co., of Tampa, for a 100-lb. sack of guano, and commenced experimenting. It cost \$3.85 for the 100 lbs. I first tried it on a bed of radishes. By the way, when you set a hen always sow some radishes at the same time. They will be then just right for the chicks when they are three or four days old, and they will soon clamor for them more than for almost any thing else. With a sharp knife shave off the tops from a bunch held in the left hand. The mother hen will instruct them.

The radish-bed was manured and fertilized, and then covered with sifted slaked lime until the surface looked white and then raked in. Just before the seeds came up a little guano was sifted on one spot across the rows; and the dark rich color and larger plants in a streak across the bed show the effect. Part of a row of onions shows the same thing; but the finest "object lesson" is a row of peas 30 feet long. I put about a teacupful on five feet at one end, and hoed it in carefully. After the first rain they took on a decidedly different color; and now when the 25-foot untreated part of the row is turning yellow, the remainder is a dark thrifty green, and Mrs. Root says she has picked more peas from that *five feet* than from the whole 25 feet that had no guano. *One cent's worth* of guano must have given five or ten cents' worth of peas to make a rough estimate. I tried it all over the garden in a similar way; and while the results are not all so pronounced, I feel sure that, used judiciously here in Florida, it is going to be of great benefit. On a few things, where the weather was too cold and wet, and possibly because I used too much, or got it too close to the plants or seeds, I killed the plants. Like many other new things you will need to experiment until you get acquainted with it.

As many of you will doubtless be inquiring where you can get it, especially a small sample, I am going to do some "free advertising" by clipping from an advertisement I find in the *Florida Grower*:

Write for free sample (enough for 40 square feet) genuine Peruvian Guano, Nature's most wonderful fertilizer, the greatest crop-producer known. Nitrate of soda. NITRATE AGENCIES CO., Savannah Bank Building, Savannah, Ga.

Perhaps I should add that all soils are not alike; and while guano gives great results on mine it may not on yours. Make careful tests on your own ground before you invest in fertilizers of *any* kind. And permit me also to add that our best authorities declare "soil analyses" amount to little or nothing. You must find out by careful tests on your own garden what *your* land needs.

At this date, March 2, we are digging the nicest Bliss Triumph potatoes we ever grew. While old potatoes are advertised at 20 cts. a peck we are getting 50 cts. Besides our poultry manure, we have used on our half-acre garden about 500 lbs. of Mapes' special potato manure at a cost of about half as much as guano, but at present we think guano is cheaper.

A NEW "DAILY BREAD."

Last October, our good friend Henry Borchers, of Laredo, Texas, sent a clipping from the (Sunday) *San Antonio Express*, with a heading "Discovered—a New Bread that will save Southwest Texas Millions." I read the article, but as I have had reason to take "discoveries" exploited in Sunday papers with a little caution, I paid but little attention to it. When I saw later that "feterita," the new bread-producing plant, was cataloged as cheap feed for chickens, I began to "take notice;" and when I saw the following in such a reliable journal as the *Farm and Fireside*, I took more notice.

Kansas had 135,800 acres of *feterita* in 1914, and yet it sprang into prominence in Kansas only last year. Besides its dry-weather-resisting qualities and early maturity, the feeding value of its grain is pronounced as practically the same, pound for pound, as that of kafir and milo. Kansas certainly snaps up the good new things.—*Farm and Fireside*.

Will some of our Kansas readers tell us if the above is really a *fact*, or is there a mistake in the figures?

Well, *feterita* is now growing in our garden; but it has been so *cold and wet* during the whole past winter (over *three times* the normal rainfall), it hasn't looked happy, nor grown very much; but whenever the sun comes out warm it brightens up vividly.

At my solicitation friend Borchers sent us some *feterita* flour and (as he is a baker) also some *feterita* bread and cakes. Breakfast food made of the flour, with some nice honey, suits me to a dot, and the *cakes* are also fine; but so far the bread does not strike me as an improvement on

the graham bread Mrs. Root makes of home-grown and home-ground wheat.* I applied to the Department of Agriculture, and received an eight-page bulletin, put out in 1914. From the last page I clip as follows:

SUMMARY.

Feterita is a sorghum from the British Egyptian Sudan, in Africa. It is a durra, related to white durra and to milo, with slender stems 4 to 7 feet high under varying conditions, erect heads, and large, rather soft, white grains.

Extravagant claims have been made for feterita by uninformed or interested persons. Experiments show it to be a good grain and forage crop, but not in any way meriting extraordinary praise. It has proved about equal to milo in yield.

All cultural operations are much the same as for milo and kafir, though certain differences are pointed out.

Feterita is newly introduced, and quite variable; therefore seed selection and improvement should be practiced in each district where it is grown in order to obtain adapted strains.

NOTE.—Since the first edition of this circular there has been considerable advertisement in Oklahoma, Kansas, and Texas of a sorghum under the name of "Schribar Corn." An examination of samples submitted to the Department of Agriculture has shown this to be nothing but feterita.

This bulletin makes no mention of it as a *bread-making grain*. Sixty years ago, when mother and I were making garden, I got from the Department of Agriculture a few seeds of "sorghum," the new Chinese sugar-cane that would grow in the North. In due time, with a home-made mill, we had "sorghum syrup." Just as usual (even at that early age), I was delighted with the new sweet, and am yet, when I can find some well made. Well, I have a dim recollection that I ground some of the mature and dried seed in the coffee-mill, and had "cakes and syrup" made of the wonderful new plant. The rest of the family, however, didn't seem to "enthuse" very much over my "great discovery."

* Since the above was in type we have been making sour-milk pancakes one-half feterita flour, and I think them fully equal to buckwheat.

In summing up, if feterita should enable us to grow chicken feed here in Florida, to take the place of wheat, it *will be* a great thing for us. We are already using kafir corn with good results, especially for little chickens.

Feterita can be grown successfully in Ohio, for The Livingston Seed Co., of Columbus, have grown it, and think so well of it they give a fine picture of a head of grain on the cover of their 1915 catalog. All reports seem to agree that it stands severe and long-continued drouth better than any other grain, and perhaps better than any other plant. It yields from 25 to 75 bushels per acre.

DASHEEN; KIND OF SOIL NEEDED, ETC.

Mr. Root:—Last year I took home (to Glen Falls, N. Y.) a quantity of dasheens, but was not satisfied with results. While they grew fairly well, by the time the fourth leaf was growing the first one would fail, and their color was never right. Can you tell me what particular kind of soil and fertilizer they need? I cannot learn from any one here. They seem to think they will grow "any old way," so, like a multitude of others, I am troubling you.

Orlando, Fla., March 22. MAY G. DEVINE.

My good friend, I regret that I cannot tell you why your dasheens should act in that way. We have no trouble here in Florida, nor in our heavy clay soil in Medina, Ohio. I think a rather damp sandy loam is best, and there should be plenty of humus in the soil—say plenty of old well-rotted stable manure, and plenty of water, at the same time providing good drainage.

THE DASHEEN IN YORK STATE.

The dasheens are received, also Rainbow corn. One of the dasheens grew last year, and was fine. I "harvested" it Oct. 26 and ate it *all*, and found it very good.

MANLEY E. BRUSH,
Hammondsport, N. Y., March 17.

My good friend, you say "*it*." Was your harvest only one tuber? You should have had a dozen, big and little.

HEALTH NOTES

OXYPATHOR DENIED THE USE OF THE MAILS.

We clip the following from the *Rural New-Yorker* of March 27:

I am tormented by an agent for "Oxyathor," which I have known to be a fraud for over 25 years.
New Jersey. Dr. C.

The doctor will not be tormented any longer. A fraud order has been issued by the Postmaster General denying the use of the mails to the "Oxyathor Company" of Buffalo and allied companies with offices at Columbus, Ohio, and Wilmington, Del., on the ground that these concerns have been defrauding the public on an enormous scale for the last six

years. An appliance was offered by the company which it was claimed transmitted oxygen into the human body and was advertised to be a cure for practically all forms of disease. The promoters were held to be "conducting a scheme for obtaining money through the mails by means of false and fraudulent pretenses." Postoffice inspectors find that in six years, from 1909 to 1914, inclusive, 45,451 such machines were sold at \$35 each, aggregating \$1,590,785. We have frequently advised against the use of this and similar appliances. Some three years ago the Oxyathor Company gave us the privilege of accepting oxyathor, "if you like, otherwise it will wipe its feet on you." It seems the Postoffice Department has made better use of it, and the Oxyathor has become the door-mat.
J. J. D.

Our older readers will recall that GLEANINGS has been fighting this thing (almost single-handed until the *Rural New-Yorker* stepped in), for more than 20 years, and we have been repeatedly threatened with "suits at law" by the different promoters of the "senseless toy." Not only that, but I have, every time I have shown it up, made some man or woman an "enemy for life," it would almost seem, because I continued to declare there was "neither sense nor science" in running "oxygen" through a wire. Just think of it—over a *million dollars* has been paid for it by sick and ailing people! It just started at \$25.00 for a senseless rig that could be sold at a profit at 25 cts.; and as if this were not a big enough profit, the price has recently been raised to \$35.00. The miserable thing has also been copied, again and again, by some vender.

Some one who had no scruples about "robbing sick people," seeing the money the "promoters" were getting, copied the thing, hence the various names for it. Some years ago I appealed to the authorities at Washington, D. C., and they sent a man to investigate; but as they didn't claim it to be a medicine he said there seemed to be no law to stop such cases. Yes, they did have a sort of *patent* granted for it, as a device that cured people by working on their *imagination*, etc.

Now, friends, there is a big moral right here that we all ought to recognize. Dear kind old Dame Nature is all the time working cures, did we but stop and recognize it. When we are feeling badly, if we go to a doctor or get something in a bottle at the drugstore, and suddenly recover, we of course give the doctor or the medicine the credit. Just 24 hours ago I took a sudden cold—almost the first severe cold since I omitted a regular supper four or five years ago, took a daily bath, etc. I had sore throat, earache, with droppings from my nostrils almost continuously, etc. Next day I had a good nap before dinner, but still felt so badly I thought *after* dinner I would really have to go to bed and stay there, and perhaps would have done so had it not seemed quite necessary I should take a trip out into the country. Well, while writing this (just before bedtime) my cold is all gone, my nostrils are clean and free from congestion, fever, etc. What did it? I don't know unless it was the ride, well bundled up, out in the Florida sunshine. Suppose, now, I had had an electropoise, and had gone through with their senseless rigmarole. What a *testimonial* I could have *honestly* given! Shall we not investigate, and try things? Sure! But take a lesson

from our various *experiment stations*. Go and visit them if you have never done so, and learn how *they* make test experiments over and over again before they accept conclusions and give the results to the world. The station folks are honest, and have no ax to grind—no object in life, except to benefit humanity.

"OLD AGE DEFERRED." FROM A GOOD FRIEND WHO WAS AN "INVALID" 30 OR 40 YEARS AGO.

Dear Bro. Root:—I have been thinking of writing to tell you that, although I am getting near my 83d birthday, I did lots of work last summer and fall—more than usual, as I have had some of our houses to repair, and the outdoor work has improved my general health very much.

As I tell it, I have spent \$200 or \$300 on the houses, and have received *one hundred dollars* in health. I am very much interested in the Home department, especially poultry and health. Mrs. Axtell's article pleased me very much. I have been for some years rubbing myself (or massaging) all over when I wake up in the night, and sleep always comes, though sometimes I massage for half an hour or more before sleep comes. I also practice deep breathing with very much benefit. I do it nearly every night.

I was interested in what you said about your daughter's Plymouth Rocks. I have one little pullet, said to be a cross between a Rhode Island Red rooster and a Black Minorca hen, which laid 28 eggs from Nov. 22 to Dec. 22. She has laid ten eggs more up to to-day, Jan. 5. I think she is something like your Buttercup, as she comes out to me, following me around and talking, and I talk back to her. I feed her extra on wheat at \$2.00 a hundred, and she eats out of my hand. We get 50 cts. a dozen here now for fresh-laid eggs.

Billy Sunday did a great work here, and I doubt if the state would have gone for prohibition but for him. He seems to have done a greater work in Des Moines, Iowa. Bible classes were started all over the city, and are still kept up. Fifty doctors organized a prayer-meeting among themselves.

Denver, Colo.

J. L. PEABODY.

"BOTH BOUND FOR THE HEAVENLY SHORE," ETC.

I recently dreamed twice in one night that I met you traveling through the country, and felt very fortunate to have a few minutes' talk.

I trust the time is coming when it shall not be limited to "a few minutes."

We are both bound for the heavenly shore, and no doubt soon will meet.

I sometimes wonder if you have trials and difficulties like myself, and if you always know just what to do. I am a class leader, steward, Bible-class teacher, and sometimes organist. I have almost three miles to go up hill to church, and have to walk all winter over terrible roads, and often through rain. I am 54 years old, and am bothered a good bit with rheumatism, and it is not the easiest task for me to get up there. However, I don't mind all the hardships. I am doing it for Christ's sake, and don't want publicity or pity. But what does hurt me is that people so seldom respond. I can't see that I am accomplishing much. I have, however, one satisfaction—my own dear children are trying to serve God.

Laurel, Oregon, Feb. 24.

S. PARR.

My good friend, "Be not *weary* in well doing, for in due time we shall reap if we faint not," and also remember who it was that said, "Inasmuch as ye have done it unto the least of one of these my brethren, ye have done it unto me." Yes, my good and patient friend, I do have trials, and I often wonder if others have as many; but had these trials not come I should not have *found* my little short prayer, "Lord, help."

TEMPERANCE

SEE FINISH FIGHT ON LIQUOR ISSUE IN 1916
CAMPAIGN.

I copy the following from the *Cleveland Plain Dealer*:

The results of the prohibition movement since December 22 are:

ALABAMA.—Legislature passed a prohibition law to go into effect July 1, 1915. Bill repassed over the governor's veto. It limits to one quart a month the amount of liquor that may be received by one consignee, and prohibits liquor advertising in newspapers, on billboards, and otherwise.

ARKANSAS.—Legislature enacted prohibition to be effective Jan. 1, 1916.

IDAHO.—Legislature has submitted the question to voters for election of 1916. Governor since has signed prohibition measure to become effective Jan. 1, 1916.

IOWA.—Legislature repealed the mulct law, leaving prohibition effective after Jan. 1, 1916. It is certain Iowa will vote on constitutional prohibition next year.

MONTANA.—Legislature submitted question to be voted on next year. Legislature desires the bill submitted should make prohibition effective Dec. 31, 1918, but the prohibitionists have refused to accept it, contending the date be Dec. 31, 1917.

NORTH CAROLINA.—Legislature passed law prohibiting delivery of intoxicants in state even for personal consumption.

SOUTH CAROLINA.—Legislature submitted question to voters for decision in 1915.

UTAH.—Both branches of legislature have voted to submit prohibition to voters.

COLORADO.—Legislature has enacted laws to enforce prohibition after Jan. 1, 1916.

MINNESOTA.—Legislature has put local option into effect.

PENNSYLVANIA.—Legislature is considering local option bill.

NEW JERSEY.—Legislature is considering local option bill.

The states in which prohibition is in effect or where statewide prohibition measures have passed, but are not yet in operation are:

Alabama, Arizona, Arkansas, Colorado, Georgia, Iowa, Idaho, Kansas, Maine, Mississippi, North Carolina, North Dakota, Oklahoma, Oregon, Tennessee, Virginia, Washington, and West Virginia. Total—18.

The action of the North Carolina legislature, following close on the West Virginia court decision which places an embargo on alcoholic liquors, is regarded here as a startling development. A bill has been offered by the speaker in the Kansas house of representatives to shut liquor out of the state.

GOD'S KINGDOM COMING.

Our good friend J. E. Miller, of Homedale, Idaho, sends the clipping below, and adds, "Praise the Lord." Can we not all join with him in his brief "Methodist shout"?

The statewide prohibition bill which makes Idaho absolutely dry after January 1, 1916, was signed by Governor Alexander at 3 o'clock last Monday afternoon. The office of the chief executive was crowded with temperance workers from all parts of the

state who desired to witness the official ceremony that came as a culmination and a victory from their efforts of several years.

Two pens were used by the governor in affixing his signature to the bill. One pen was presented as a souvenir to Mrs. W. S. Chipp, of Boise, the president of the Women's Christian Temperance Union of Idaho, and the other was handed to W. J. Herwig, state superintendent of the Anti-saloon League.

Praise the Lord!

SIGNIFICANT FIGURES.

From the last United States census we learn that the wet state of Nevada had, in 1910, 353 prisoners for every 100,000 of her population, while her dry neighbor, North Dakota, had 63. Nevada had 194 paupers for every 100,000 population; North Dakota, 14. Nevada had 282 insane people for every 100,000; North Dakota, 108.—*Home and State*.

SOME EXTRAVAGANTLY KIND WORDS FROM A BROTHER IN FLORIDA.

Dear Friend:—I am trying in my poor way to keep up with your papers called *Our Homes*, as they are of much importance to me. I find myself without words in stock to express to you how I appreciate the feasts it brings to my soul. They are just sweet, for I am sure that they have been given to you from a higher power than mere education. "Lord, help!" means much. I realize this as being a more than true fact, if, possibly, "Lord, help!" has been heard by the loving Savior many times. I can say of a truth that Jesus does answer prayer.

Now let me suggest to you that Jesus is a polite clerk for God's great storehouse of goods, and is just ready and waiting for a customer to rap, or ring the phone bell, and then "right then the goods are delivered"—no climbing up and down the shelves to look for the number the customer calls for. Jesus is fully up to this wonderful house of plenty, and, best of all, he does not *cheat* customers who deal with *him*. When once a man gets *acquainted* with this wonderful Jesus (the principal clerk), he never becomes displeased, for he knows just what size of garment and style will fit, and he can see you, even away down the dark road, coming to purchase a wedding-garment. Just call over the phone, and your order will be filled that same day. In fact, I believe I can say Jesus (without fear or doubt), will even fit it on you before you can hang up the receiver.

I trust you will not think me boasting when I tell you I ordered a robe of righteousness, pure and white, washed in the blood of the Lamb; and, praise his holy name, it just suits me; and, best of all, I feel sure that I can wear it six days in the week, and then it is also ready for Sunday service. Thank God for his promptness in filling the order. He has been a friend to me. I am sure if either of those skeptics you referred to will call for a Christlike "tailor-made" suit, so to speak, and call in *dead earnest and faith*, Jesus can please them, and they will be *ashamed* of the one they are now wearing. Can't I hear you say, "*Amen, a-men*"? May God help you in this contest with such characters as you are now having to contend with. Dear brother, you have got my vote in the contest.

I want you to pray for me, and faint not. Ask God, in his all-seeing and all-knowing power, to deliver me. This is a wonderful knowledge, if it is his will, for me to know and understand his biddings and the scriptures. "For in them ye think ye have eternal life, and they are they that testify of me." Pray for me. I need the prayers of all God's dear children. I thank God, time after time, for just such men as A. L. Root.

Sanborn, Fla. Oct. 12. CHARLEY C. LANGSTON.

Clover Prospects for this Season

REPORTS are somewhat conflicting. Some say that clover looks well, while others say the weather has been too dry. In this locality we have not had quite enough rain to insure a good crop of clover honey. The spring has been favorable for building up colonies.

Late California Rains

JUST as we go to press the following report has been received:

The California situation has improved with a rain ranging from one-quarter of an inch to one inch and some places more than that in the higher mountains.

This will put an altogether different complexion on the prospects of some localities, which had begun to dry out with hot winds. The weather for the last ten days has been rather cool for the production of orange honey, though several people report that they are taking out honey in liberal quantities.

Idaho Not Without Foul-brood Legislation after all

JOSEPH J. ANDERSON, of Salem, Idaho, in one of his recent letters, in referring to the fact of the governor having vetoed their foul-brood bill, says the beekeepers of the state are not without protection after all, but they needed something better. Fortunately they have an appropriation of \$3000 to put the old law they have into effect.

Big Quadruple Winter Cases vs. Individual Double-walled Packed Hives

THE past winter's experience does not clearly show that these big winter cases are ahead of the double-walled so-called chaff hives. In one yard the big ones showed a marked superiority over the individual double hives. In another yard there is no appreciable difference. The fact that we had so much aster honey last fall has complicated the results, and it is therefore a little difficult to make any definite assertion.

Where there are good stores and a fair colony, big winter cases are ahead in that they have much more brood than the individual double-walled hives.

How the Bees over the Country have Wintered

REPORTS thus far received from over the country show remarkably good wintering. There are a few reports, where bees had aster stores, showing that there was from 25 to 50 per cent loss, and hives badly spotted with dysentery. The losses seem to be largely in the aster districts of northern Ohio than anywhere else. Our own loss will run about 35 per cent among colonies supplied with aster stores. There was no appreciable loss among bees having good stores.

We shall be glad to get reports from our subscribers as to how bees have wintered in their respective localities; and if there was any considerable loss, whether the spring has been favorable enough to compensate in part for this loss. This information will be very interesting and valuable, as it will have a bearing on the price of honey this coming season.

The Folly of Spreading Brood at this Time of the Year

VERY often when a premature warm spell of weather comes on, lasting for a couple of weeks, the temptation is very strong to hasten brood-rearing, either by unwise feeding when the bees have plenty of stores or by spreading brood. The novice is very apt to conclude that the bees will increase faster if he puts a frame of empty comb down in the center of the brood-nest; and if the warm weather continues, with no cool nights, the practice may do no harm, and it may do some good. But as a general thing old Dame Nature has a fashion of bringing on one extreme after another. A

warm or hot spell out of season is quite likely to be followed by a chilly or a cold spell of weather. It is then that the practice of spreading brood results in almost irreparable damage to the colony. While the bees may recover, the split brood-nest causes a large amount of brood to chill and die; and the result is very much worse than if the bees had been left to their own sweet will.

Luther Burbank and his Recognition of the Honeybee as a Pollinating Agent

QUITE incidentally we have learned, as we approached the home of Luther Burbank, the plant wizard of the world, that in the making of some of his new creations he is in the habit of getting up at 4 o'clock every morning, or before the bees get out to modify the results. He has often spoken of the bees as a pollinating agent; and did he not recognize their power to modify plant life, he would not get up so early in the morning to mingle the pollen in an artificial way in order that he may secure some creations that nature, if left undisturbed, would not produce. Indeed, we are told he keeps bees for the very express purpose of helping him to bring out some of his wonderful works in the plant world.

How do Bees Smell?

JUST as the study of human traits and faculties is based upon accurate researches in the senses, the study of the psychology of the honeybee should begin with investigations of the sense organs of bees. Unless their anatomy and functions have been carefully determined, we can never reach a clear understanding of bee behavior. The habits may be observed, but the reason back of them can never be grasped by one unfamiliar with the way they receive their impressions of the outside world.

If any of the three senses of sight, sound, and touch can be picked out as more fundamental in man than another, it is sight. With the bee the sense of smell is probably the most important within the darkness of the hive but outside it is of secondary importance. The seat of this sense, scientists hitherto have been placing in the antennæ, one writer even claiming to have located the segments in which the power of detecting enemies arises.

According to N. E. McIndoo, Ph.D., of the U. S. Department of Entomology, the seat of the olfactory sense is not in the

antennæ but in certain olfactory pores, at the base of the wing and the joint of the leg. In a noteworthy contribution to the psychology of hymenoptera entitled "The Olfactory Sense of the Honeybee," he details an extensive series of experiments carried on with normal and mutilated bees to discover wherein lies their appreciation of odors. Bees deprived of antennæ were abnormal in every way. There was nothing in his experiment to indicate that the antennæ play the slightest part in smell. On the other hand closing certain of these pores with varnish increased twelve times the length of time the bee ordinarily took to react to strong odors. From these results he summarizes that the antennæ can no longer be regarded as the seat of the sense of smell in insects.

In a criticism in the *American Bee Journal*, Dr. Bruennich believes that these organs which Mr. McIndoo featured are merely protective against injurious gases, and that the antennæ are the seat of the senses detecting the presence of honey and of enemies.

Difference in Honey Production between Two Apiaries Two or Three Miles Apart, and Why

It is a well-known fact that there may be a great difference in the yield of honey between different outyards. One yard, for example, may yield 100 lbs. of surplus clover, and another, not two miles away, will furnish almost nothing. Sometimes the difference is attributed to the soil; but when the two yards have yielded about the same amount in previous years, we must account for it on a different basis.

Just a few days ago two farmers near us complained of weather conditions on the same day. One had had so much rain that the ground was so thoroughly soaked he could not cultivate, and the other, not more than a mile and a half away, said his ground was so dry that he feared that his crops would be short. Suppose, for example, both men had been growing alsike and white clover. It is easy to see why in the one case bees on one farm would get a crop of honey while those on the other farm would get nothing. These local showers have a way of thoroughly wetting down one farm and leaving the other farm high and dry. Then, the failure of one beeyard and a plentiful yield of honey in another can often be explained by the amount of moisture in the soil.

There is another cause: There will be winter killing of clover on one farm where

the land is low and wet, where on another farm a mile or two away on high ground that is comparatively dry, there will be no winter killing. On the latter farm bees may do well; on the former there might be almost a failure of honey.

The A B C of Composition

THE editors of GLEANINGS have printed a small folder for free distribution entitled "Suggestions to Contributors," designed to furnish contributors and would-be contributors a few hints on the composition and general get-up of their articles. So much ignorance seems to exist regarding the manner in which a manuscript should be prepared for the printer that these instructions should be welcomed by the writers for GLEANINGS. While the thought is the main thing, it is true, nevertheless, that a well-written article commands a higher price than one that is carelessly prepared.

The college professor who reads in this circular that all sentences should begin with a capital letter should not allow his feelings to be hurt. The little instruction is given in elementaries because elementary reminders are just what a great many writers need.

If the contributors follow these instructions the editors will be happy, typesetters will bless them, and they themselves in the end will be gratified at the improvement.

The Massachusetts State Board of Agriculture and its Advice to the Fruit-growers on Spraying

THE Massachusetts State Board of Agriculture is sending out a large colored poster in bold display type, containing a set of instructions to the fruit-growers of Massachusetts. At the very beginning is a bold headline, "Are you spraying at the right time, or are you spraying at all?" Another line says, "Are you killing the bees that are setting the fruit for you?" Down below this there are plain and specific instructions on when and what to spray with. It makes very emphatic the fact that the trees should not be sprayed while in bloom, and then adds, "If the nectar and pollen they (the bees) are after are poisoned at the wrong time (during blossoming) they are liable to be poisoned, and less fruit will be set." Then in black letters appears the following: "Never allow your trees to be sprayed while the large pink or white blossoms are still on them, for the job will not be as well done. Less fruit will be set, and

many bees may be killed." This is not from a beekeeper, but from the State Nursery Inspector, H. T. Fernald.

This poster is one of the best things we have seen. It is brief and to the point, and cannot help being of great benefit to fruit-growers and beekeepers alike. Other states would do well to send for a copy and get out one similar to it.

A New Department for Southern Beekeepers

There have been many requests for a department in GLEANINGS representing the southeastern part of the country. The beekeepers have felt so "left out" that they finally brought their requests to a focus—with the result that "The Dixie Bee" starts with this number, and will appear in the first number each month.

GRACE ALLEN

Our readers who have been enjoying the delightful poems by Grace Allen will be glad to know that she has consented to edit this new department. Mrs. Allen is hardly a beginner, but she does not wish to pose as an expert—just yet. Her department will be of special interest to the beekeepers in the great Southeast, to the beginners in all parts of the country, and to all who love good poetry. Besides being an enthusiastic beekeeper herself, she is vice-president of the Tennessee Beekeepers' Association and will be in close touch with a large number of prominent honey-producers.

Aster Stores in and about Medina and Elsewhere

IN this issue, page 352, J. L. Byer reports good wintering on aster stores at one of his yards. In this locality the colonies that have had access to these kinds of stores (or what seemed to be the same) showed up dysentery and spring dwindling. Some colonies died outright, and many are weak. When the colonies had good stores, free from aster, there was universally good wintering.

We hardly know how to account for the difference in the asters of Canada and those in the vicinity of Medina, unless there is some other weed that grows in Medina Co. that does not grow in the vicinity of the

Byer bees. This raises the question whether aster honey was the cause of our trouble, or something else that bloomed at about the same time. As there are many different kinds of asters, there are of course several different kinds of aster honey. Some of them may be good while others are bad for wintering.

It will take further investigation before we can arrive at definite conclusions. But A. J. Halter, in whose vicinity we had a couple of yards of bees in the aster swamps of Summit Co., warned us to look out for those aster stores. We knew the general bad reputation of aster honey. Those that had the most of it were sent down to Virginia. The rest were left at Medina, with the result as already stated.

Massachusetts Apiculture

THE president of the National Beekeepers' Association, Dr. Burton N. Gates, of the Massachusetts Agricultural College, is the author of a paper on "Beekeeping in Massachusetts," which has been published as Bulletin No. 75 of the Federal Bureau of Entomology. A sketch of this nature, not attempting too much, is particularly valuable for the study of conditions in a locality, and takes its place among a number of similar highly valuable reports of state beekeeping, which, taken together, give a comprehensive view of the situation in the whole country.

Colonial apiculture had its beginning in Massachusetts as early as 1644, but we hear little of it from that time until the beginning of the last century, when what little progress it may have made all but succumbed to a series of attacks by disease. Langstroth's epoch-making invention in 1853 transformed beekeeping in this state just as in all the rest.

Dr. Gates believes Massachusetts needs "fewer but more proficient beekeepers who will undertake the work along this line." The reported average of $5\frac{1}{2}$ colonies to the beekeeper is far too small; but if it were very greatly increased many would have to go out of the business on account of a lack of forage for the bees. His figures reveal the fact that half the beekeepers quit the business after about five years of the pursuit. Probably this proportion would hold general in other states.

The room for improvement is shown most strikingly in the conclusion that about one-fourth of the beekeepers still hang to the use of old box hives. With the advent of the modern professional beekeeper, with his standardized equipment and efficient meth-

ods, this figure is doubtless approaching zero as the limit.

The author reviews the phase of beekeeping most peculiar to Massachusetts. In 1909 there were at least one hundred and eighteen greenhouse cucumber-growers. Each of these used about eight colonies to an extensive crop. He believes over a thousand colonies are destroyed in this manner every year, since each colony is fully ruined after a year of use. The waste of this condition could be improved by practical beekeeping methods among the cucumber-growers, and a great deal of expense saved.

The Beekeepers of Imperial Valley, California, not "Dogs in the Manger." A Wonderful Bee Country

WE had the privilege of spending one day in the wonderful Imperial Valley of California. This valley is surrounded by miles and miles of desert and mountainous country that can never be irrigated, for the simple reason that it cannot be reached by water. In fact, the valley is a mammoth oasis of four million acres under cultivation, with two more million to follow when water can be got on to it. The soil is wonderfully productive—deep and rich; in fact, the territory has been called "the little Nile of the Western Hemisphere." We doubt if there is another spot in the world its superior. It will grow practically every thing. It is one of the most wonderful alfalfa districts in the United States; and that means it is a wonderful bee country. But, like all of these bee paradises, it has its drawbacks. It is excessively hot there in the summer time. It is already overstocked with bees and beekeepers. The alfalfa honey there is darker than the same kind of honey produced in Nevada and Colorado, and hence brings a lower price.

The fact that Imperial Valley is quite isolated by a dry stretch of forty miles all around, has enabled the beekeepers of the valley to prevent the importation of bee disease. If it is once free of European and American foul brood, there will be no danger of either of those diseases getting a foothold, providing the importation of bees can be stopped. Accordingly, taking advantage of the California county foul-brood law, the beekeepers of Imperial Valley have stopped all importation of honeybees into their county that have either had disease or which came from a locality where disease was present. The unpleasant duty and responsibility of enforcing this law fell on Mr. A. F. Wagner, foul-brood inspector of

El Centro, in the very heart of that wonderful country; and because he has enforced the law to the letter he has called down on his head the wrath of the beekeepers of other counties. Indeed, the beemen of Imperial Co. have been accused of playing the part of the dog in the manger. It is but natural that the "outsiders" should complain of unfairness. On the other hand, when one talks with the "insiders" he can see that there is some justice in their claims.

We met several prominent beekeepers of the valley and discussed this whole question. They deny that they are opposed to the importation of bees from other localities providing those bees are healthy themselves, and providing also they come from locations where there are no bee diseases. They freely acknowledged that they had stopped shipments into their valley because the bees in question came from localities where bee disease was rampant, and they insist that they will do it again. Their condition, they contend, is different from that of any other county in California in that it is surrounded either by barren mountain ranges or deserts. There is no possible chance of bee disease coming there unless it is imported by direct shipment.

Their valley is practically free of disease, although occasional cases of it crop out here and there; but through the systematic efforts of the inspector, Mr. Wagner, they are hoping to stamp it out entirely. That they could never do if they allowed indiscriminate shipments into the valley.

They admit that they have a wonderful bee country, and say that any man who desires can come into their midst and bring bees, providing those bees can show a clean bill of health, and providing it can be shown that the locality whence they come is free from disease.

Later on we shall be glad to present some photos of some of the leaders in that valley, and some of the wonderful erosion that has taken place in that country when the water broke loose and filled up the Salton Sea Basin. This was formerly a barren hot dry basin below the level of the sea. It is now, owing to a blunder of an irrigation company, a big inland sea. Hundreds of fine ranches or farms were literally washed away and a new river bed established. This "blunder" was both a blessing and a curse to the valley. Those who were not hurt do not care, and those who were have filed damage suits. When boys or men fool with a hole in a dyke or other barrier to a big water supply they should be careful what they do. In this case millions of dollars of damage was done.

Successful Co-operative Experiments

THAT the beekeeper who looks beyond the end of his nose is the man who gets the big honey production is shown by the results of experiments reported to the Ontario Provincial Apiarist. A unique policy is that of the province in sending out standard material and directions for carrying on a definite experiment, to all who desire to make the experiment and accurately report the results. While not listed as such, the whole plan is in itself an experiment to prove that the beekeeper interested in the progress of his science actually averages more than twice the efficiency of the indifferent fellow. This was shown in reports from 541 experimenters.

These 541 had an average of 28.6 colonies each and in experience varied from one year to forty. Hives of every variety were reported, but more than half were Langstroth. Pure Italian colonies nearly equaled hybrids and blacks together, a large increase over last year.

The experiments concerned prevention of natural swarming in comb and in extracted honey production by holding the colonies together, the prevention of natural swarming by manipulation of hives instead of combs, the method of spring management, special inquiries in races of bees, and the "smoke" method of queen introduction. The last proved entirely satisfactory with two-thirds of the experimenters.

Experiments for 1915 include the starvation and "smoke" plans of introducing a laying queen to a whole colony, shipping and introducing combless packages of bees, and the use of the wire-cloth bee-escape boards for removing bees from supers.

The U. S. Weather Bureau Maps; How they may Enable us to Fore- cast the Honey Yield, both in the East and West; What shall the Harvest be for 1915?

WE have been getting from the general Government, for some time back, at the suggestion of Dr. E. F. Phillips, of the Department of Agriculture, daily weather-maps showing the isothermal lines of temperature in every portion of the United States, the direction of the wind, and the height of the barometer. The isothermal lines are shown by red lines giving the temperature of every day of the year at 8 o'clock in the morning; and it is astonishing how the isothermal lines will move from north to south. For example, on April 20

the temperature at Portland, Me., was the same as that at Atlanta, Ga.; and the same line on the same day ran through Chicago and Kansas City, almost around to San Antonio, Texas. In other words, it was just as warm in Portland, Me., and Chicago, at 8 o'clock, April 20, as it was at Atlanta and San Antonio. On April 18, the same isothermal line of 50 degrees started from Portland, went down to Asheville, N. C., away up to Chicago, Alpena, Mich., and clear up to the northern part of Lake Superior.

The barometric changes are no less freaky. The area of precipitation or slight rains is shown by a dark shading. Very often when we get a rain at Medina we wonder if there was only a local rain, or whether it covered a large portion of the United States. By consulting these maps two days afterward we can tell exactly how far our Medina rain extended. Two weeks ago the maps showed that the April showers covered all the eastern states, the entire lake region, and extended down to a narrow line covering the territory immediately surrounding New Orleans. A few days afterward this area of precipitation kept getting smaller and smaller until it disappeared altogether.

During the last few days it has been a little cloudy, and we hoped it was going to rain, for our rheumatic bones seemed to feel that way. There was a very light sprinkle with cloudy sky. These Government maps showed that for over a week almost the entire United States was showing a high barometer—that is, no rain. In fact, the map was practically white all over, and it has been so for a couple of weeks back. (White means no precipitation.) We now know without any guesswork that there has been no rain to amount to anything in the United States for the last ten days. Already letters are coming in to show that it is getting dry. The farmers in our locality are complaining that the wheat needs rain. When wheat suffers, the clovers suffer. It is not too late yet for rains to come so that the clovers will yield a crop of honey; but we are getting near the danger-line. Unless rain comes within a few days, and that, too, over a large part of the United States, there will not be much clover honey in the United States. Already we hear of forest fires in Michigan and Pennsylvania, and these fires rarely occur unless it is getting pretty dry.

The failure or partial failure of the clover crop will have a decided tendency to boost prices on honey. The western beekeepers in the irrigated regions may well smile, for what is bad for the eastern brethren is often a good thing for the western beekeepers.

But Mr. Frank Rauchfuss, an authority on Colorado alfalfa, says there has been an insufficient supply of snow in the mountains; and when we saw him he feared that the alfalfa yield would be curtailed somewhat, if not short. In this issue our California correspondent speaks of its being a little dry in the sage region, notwithstanding the heavy rains early in the season. Our Weather Bureau maps show that there has been but very little rain in the sage districts of California during the last week or ten days. We were notified when on the western Coast that there might be ever so much rain for the sages early in the season; but unless there was a good shower just before or about the time they come into bloom the sages might fail. It is not too late at this writing, April 21, to get the needed rains in California and the central states.

Later, April 23.—Some fine rains with warm weather have come in the nick of time.

Still later.—General light rains on the 22d fell in northeastern Ohio, Indiana, Illinois, Kentucky, Tennessee, Missouri, and as far south as Alabama. There were also rains over the whole of California. Whether these were enough to help out the sages and the clovers we cannot say. There were no rains for the same period in eastern United States, comprising New England, New York, Pennsylvania, and Michigan.

April 25.—The rains have come for New York and Pennsylvania. Michigan still dry.

PROSPECTS IN THE CLOVER AREA.

In our next issue we shall be able to tell the story. The practical bearing of this whole thing is its reference to the honey market—that is to say, the Weather Bureau maps, we hope, are going to enable us to forecast the honey crop, both east and west; but it should be said that in the irrigated regions, and where high mountains are not too far away, but high enough so they hold snow the year round, the honey crop is almost a sure thing; but in order to hold snow the mountains must be somewhere about two miles high above the level of the sea. This is one reason why the Rockies and the Sierra Nevadas furnish such immense quantities of irrigation water from the melting snow for the valleys beneath. Very often there will be a severe drouth in the eastern states when the constantly melting snows of the mountains cause the valleys to blossom like the rose of Sharon.

Dr. C. C. Miller

STRAY STRAWS

Marengo, Ill.

ANOTHER sign of laying workers may be added to those on page 312. It is to find an egg laid upon pollen.

F. GREINER, p. 333, says bait-combs result in pollen-laden sections. They don't here, friend

Greiner.

G. M. DOOLITTLE's description of a piping queen's performance, p. 312, is the best I've ever seen. But I'm surprised that he has never "heard a 'pipe' from any queen while she was on any other place than a comb." A queen often pipes in a cage with no comb.

EUGENE SECOR has had none of the poetry dried out of him yet. In a note dated March 16 he says: "Every thing here is yet asleep. No alarm has been sounded by robin or bluebird. But the bees in cellar have shaken off their winter stupor, and are fretting to frolic among fragrant flowers."

CHALON FOWLS quotes Ira D. Bartlett as saying 90 per cent fail in beekeeping, and exclaims, "O Ira!" Then he coolly reads out of the list of beekeepers all farmers keeping a few bees who have a hundred times more capital invested in their farm or stock. O Chalon! Just how many colonies should a man have before he should be called a beekeeper, anyway?

ASTER stores are blamed for winter losses. Why don't you train your bees to let asters alone? Asters are plentiful here, but my bees practically neglect them, and they came out of cellar in fine condition April 6. [It is not every year that asters yield honey; and it is not every locality where they secrete much nectar. If we had fed our bees on good sugar syrup or good honey and kept them at home last fall, instead of hauling them ten or twenty or even fifty miles to the aster swamps, we should have been better off. The asters are all right; but the stores, as a general thing, should be used for breeding, and not as a winter food.]

DENATURED sugar is of great interest to European beekeepers because of the high duty on sugar. But how much could we gain that way? I wish, however, there were a law against feeding bees any thing but deeply colored sugar, so it would show plainly if any of it should get into the surplus. [Members of the National convention at Denver thought it was wise to go slow in making recommendations to the

national Government to provide for denatured sugar to be used for feeding bees. Possibly there would be no very great financial gain—especially so when sugar reaches its normal price after this senseless war is over.—ED.]

L. S. CRAWSHAW, that breezy writer of the *British Bee Journal*, p. 95, says: "Precisely what some few of us 'retrograde writers' have maintained in spite of abuse is that early queens, raised under the natural-swarming impulse, are the best." Now, that isn't a bit kind in you, L. S., to be scattering doubts and fears among my hopes and longings. Here I've been rejoiced to find now and then a colony quietly superseding its queen, with no inclination toward the swarming impulse, natural or unnatural, but bending its whole energy toward piling in the honey, and thinking that a queen resulting from such a supersedure was equal to the best, and now you would have me believe it would be still better with some "impulse." "Didn't happen to think of that sort of case?" All right; send around a small boy with an apology, and we'll be friends again. I'm heartily with you, that when, under the most favorable conditions, a colony rears queens in preparation for swarming, the queens reared under that "impulse" cannot be improved by the intermeddling of any two-legged creature so long as the young queens are reared from that same old one. But please remember that, under natural conditions, *every* queen is superseded by the bees before she dies, and that the superseding impulse is just as natural as the swarming impulse. Swarming may or may not be, but supersedure there *must* be if the colony is to continue. So when it's the regular business of old dame Nature to rear queens for superseding, wouldn't you expect a good job?

Now let me say what further I believe, and I'll be glad if you agree. Take a broad view of the field, or, rather, of the apiary. Here are 100 colonies, having all degrees of inclination toward swarming. I can leave them to their own sweet wills year after year, and each will have a queen reared under the swarming impulse. Or, remembering that however good the swarming impulse may be for queen-rearing, the less of it the better for honey-getting, I can take the matter into my own hands and rear queens from some colony with never a swarming impulse, but strong on storing. I believe I can get bigger crops by taking the latter course. I believe I have done so.

NOTES FROM CANADA

J. L. Byer, Markham, Ontario

I have just returned from visiting the north yard referred to at different times during the past winter, where the 250 colonies were wintered mainly on aster honey. The bees had no cleansing flight wintered mainly on aster honey.

April 7, and, much to my surprise, every colony in normal condition last fall is alive at present, and not a spot of dysentery in the whole apiary. More particulars later.

At this date (April 12) it looks as though bees have wintered better than anticipated in my Notes for April 1. Heavy losses are reported only where little feeding was done last fall, and in some cases where natural stores were bad. Our own losses seem to be confined to two yards where about fifteen colonies have perished, and in these cases abundant stores were present, but granulated solid. The bees broke their cluster early in March, with combs solid with this poor stuff.

Mention is made on page 173 about a ten-pound pail, used for a boiler for a steam-heated knife, bursting and severely scalding the person using the knife. The warning is not out of place, as one needs to be careful. During 1913 we had a similar experience, but no one was hurt. We use a small kettle, and the top is fitted in tightly by placing a few thicknesses of cotton under the cover and then pressing it in. Once the knife became clogged, and this top acted as a safety-valve, blowing out so forcibly that it went to the roof of the building. Mrs. Byer was sprayed a little with the hot water, but received no injury.

This is the time of the year when letters come in asking about clipping queens. The subject has been debated so much that it is pretty well settled, and the verdict is apparent from the fact that about 90 per cent of the commercial beekeepers, at least, follow the practice. Just a word of warning to beginners on this question: Do not clip part of the queens in the apiary and leave the rest. Clip all of them or none. Space forbids at this time giving more reasons for this advice; but if the beginner is at all doubtful as to its wisdom, let him try the partial method; and if a bad swarming season should ensue, he will understand all about it by the end of the season.

My father left North Carolina for home April 7, and at that date the bees there were working on the soft maples. On April 8 our bees (at home) were getting pollen and nectar from the same source. This is an unusual condition indeed, as other years when father has been in the South there has been at least a month's difference in the time of bloom of south maples as compared with us in Ontario. If this has been general all over the South I would surmise that it has been a poor year to move bees down there to have them build up for increase and moved back north again later in season. I sincerely hope conditions have not been so backward in the vicinity of the Dismal Swamp. Vegetation was further advanced on the date mentioned, in the vicinity of Cincinnati, than it was twenty miles from Asheville, N. C.

Glad for the caution to shippers of queens and bees by the pound, as lately given in "Special Notices," Feb. 15. Especially should shippers of bees by the pound be careful in sending bees long distances. While many have come to Ontario in good condition, many have come otherwise, and shippers should either be able to prepare the bees so as to be sure of safe arrival, or else be prepared to make good all losses. One of the great troubles is getting quick clearance from the customs office nearest the beekeeper getting the pound packages; and from past experience, if getting any such packages I believe I would have them sent to Toronto and then make it a point to meet the shipment and bring them out the twenty miles by auto or other conveyance.

In 1913 a young man near me got quite a large shipment from a point as near as Michigan. They came to Toronto; and by reason of a lot of red tape, they actually lay there for two days. The result was a lot of dead bees; and although claims were made on the express office, up to this time not a cent has been paid to the buyer of the bees, and he just lately received a letter saying no payment would be made. For a private individual to get after an express company is out of the question, so I suppose the beekeeper will have to bear the loss.

"What a difference between the North and the South!" exclaims our friend from Texas, page 222, March 15. Yes, there is

Continued on page 355.

BEEKEEPING IN CALIFORNIA

P. C. Chadwick, Redlands, Cal.

There is little danger of disease from stray swarms if hived on foundation. The lapse of time before the queen can begin laying removes any likelihood of disease being carried.

Hot, dry, electric weather the past two weeks has caused beekeepers some worry. Some indications of rain are now developing, and it is to be hoped we get sufficient to keep the surface moist.

Out of all the colonies requeened last season, not one queenless colony has been found; while ten per cent of the two-year-old queens have disappeared during the winter and spring, leaving fertile-worker colonies in most instances.

Economy in bee time is really an important factor. Weeds in front of hives, an entrance too small, an alighting-board too narrow, and hives set high off the ground, allowing the wind to toy with them, all have a tendency to retard their progress.

After being free of foul brood in my apiary for five years, I have suddenly discovered a case of American. They were promptly destroyed, and I fear no further trouble. Black brood is cropping out badly in many sections, some places being extremely bad, and apparently hard to get under control.

While I was shaking combs to get the queen below an excluder, a considerable amount of nectar fell on a board which I was using in front of the hive to catch the bees as an alighting-board. It was very thin, and I supposed it would evaporate, leaving only a sticky place on the board. To my great surprise, after it had remained in the sun all day I found it to be thick heavy honey with not nearly the amount of decrease by evaporation I had expected.

Will wax-moth work on wet combs? Now you novices in the business, be careful. Here comes a man who says moth will not work on wet combs; another says they will. What

are you going to do? Take a bit of advice from me. Put your combs away dry and clean, and have them in shape when needed. Wet combs catch dust and dirt, harbor filth, and will be riddled by moth just as quickly as dry ones if there is food for moth in them.

I have been trying out a new scale for buying swarms. It does not pay to give a fixed price for swarms of all sizes. Some are worth no more than half the amount of others. Their value differing so much at different times of the season, it is hard to make a season's scale; but the idea is to pay a certain price up to six or seven pounds, after which an increase of one-half is added to each additional pound; for example, ten cents per pound for the first five pounds; fifteen cents per pound for each additional pound up to ten pounds, then twenty cents per pound for all above ten pounds.

There has not been so much swarming in recent years as is now going on. Every colony seems bent on swarming, whether it be in the side of a house, a neglected one in the back yard, or those under daily care. Swarms are flying in every direction, entering houses by the score, and causing the timid housewife much worry. I have captured sixteen during the past ten days, some by paying a small sum in cash, and some by answering the pleadings of people begging to have them taken away. I attribute the trouble to the advanced condition of bees when the nectar began flowing freely, which seemed to set them wild for swarming.

There has never been, to my knowledge, a greater amount of nectar in the orange than at the present time. Bees are working it to the limit, and I look for the greatest crop of orange honey ever harvested in this state. The sage is not so promising as a few weeks ago, and I fear there will be much less from this source than has been figured on by many. Bees are flying miles over good sage-fields going to the orange. The plants seem to be less healthy than at one time, and the sage weevil is getting an early start with its work. Bees are paying very little attention to sage, but this may be partly due to the excessive amount the orange is yielding.

Grace Allen

THE DIXIE BEE

Nashville, Tenn.

So many beekeepers in the great Southeast, and not a department in all GLEANINGS we could call our own! And the North and the West and the East, and the Southwest and the far West and the Northeast, all there at the gathering of the "localities," and no corner for a Dixie bee to hum! It was after the convention of Tennessee beekeepers that we cried out, and the editors heard our cry and said, "You, too, shall have a page." And that I understood; but when they said, "*You* shall have the page," that I could not understand. Only the editor can explain that. For in all frankness I am not a beekeeper of great experience. In fact, I am distinctly in the beginners' class. But, if my suspicions are correct, that may be one reason the editor asked me to take this page. Not only a new section, but also a new class, they would thus have. So while this page is to be especially for and about the Southeast, it will also aim to be of interest to beginners, and to women beekeepers—a sort of Dixie bee that hums contentedly within its proper geography, but waves its wings tenderly over the amateur and the woman apiarist.

A high-school teacher, writing back to her pupils from Europe, once said, "I hope you may all take this wonderful trip some day; but my solemn advice is, *never do it for the first time.*" If one could only write a page once a month for GLEANINGS, and never do it for the first time!

CLOVER PROSPECTS AFTER THE COLD SPRING.

Our winter might have been borrowed from the North, so long and cold it has been. Even as late as March 30 it snowed all day. But throughout this part of Tennessee the bees seem to have wintered excellently—unusually well, some beekeepers judge (most of them on aster honey at that). But they are late building up. In

one of our hives we could not find the slightest evidence of brood-rearing as late as April 4, though another right beside it was well filled with eggs and very young brood. All we looked into had plenty of stores.

Any way, I fancy we shouldn't have opened our hives that day, as the bees, with not a blossom in all their world, went wild over the honey odors, and the little yard was presently in an uproar. We apologized to the defenders, expostulated with the robbers, piled straw over much-contracted entrances, sprayed it with carbolic water, and recorded another lesson learned. To-day (April 7) the old plum in the back yard is in full bloom, and the bees are making it ring with music.

We are hoping, modestly, for white clover this year. Last year there was none in this section, owing to the drouths of 1913 and 1914. There are no blooming prospects now; but from adjoining counties come reports that it is showing up a little, and surely I saw signs of some to be, out on the commons where this end of town runs into country. One of our most successful beekeepers fears that

the bees have been so held back by the late spring that they can scarcely build up a strong working force in time to do much good if the clover does materialize. But we are all hoping.

TENNESSEE FIELD MEETINGS.

"What is an association for, if not for co-operation?" asks Mr. W. B. Romine, of Pulaski, Tenn., the new president of our state association. And that seems to me a splendid association spirit. Some of the members in this neighborhood are going to try getting together informally several times during the approaching summer to get better acquainted and talk shop and learn, learn, learn. A bore to those who already know? But of all whom I know, those who

AN INVITATION

In May come down to Tennessee,

Tennessee, Tennessee!

In May come down to Tennessee—

It's honeysuckle-time!

We'll drive among the winsome hills

Where tangled honeysuckle fills

The cup of scent that spills and spills

In honeysuckle-time!

The mockingbirds will all be singing,

Redbirds flashing round and flinging

Flaming colors through the springing

Honeysuckle-time!

The murmur of the bees, that slips

Along the wind from blossom lips

Will thrill you to your finger tips

In honeysuckle-time!

In May come down to Tennessee,

Tennessee, Tennessee!

In May come down to Tennessee—

It's honeysuckle-time!

You'll think the magic of the bee

And wine-like air and sun-bright tree

Is fairland. *It's Tennessee*

In honeysuckle-time!

know most are most eager to know more! It's only a very little knowledge that's a satisfying thing. With this plan in mind, A. I. Root's account of the weekly meetings of beekeepers in Florida was particularly interesting. (March 15, p. 251.)

Mr. Buchanan, the secretary of the state association, informs me that some such well-known beemen as Dr. Phillips, Prof. E. G. Baldwin, J. J. Wilder, Adrian Getaz, and others will be in Chattanooga April 28, 29, in connection with the Southern Educational and Industrial Conference. That surely sounds attractive.

FOUL-BROOD LEGISLATION SAFE.

The beekeepers of Tennessee who were not present at the convention may not know what a splendid fight was put up in Nashville in the winter, when some of the legislators tried to repeal our foul-brood inspection law. Dr. J. S. Ward, the state inspector, was on the scene day after day, with statistics and general bee-booster literature that was eye-opening to some of our law-makers who had not guessed the real value of bees. And with the help of Mr. Ben G. Davis and a few others Dr. Ward and the Dixie bee won the day.

* * *

Over in Winston-Salem, N. C., is a new organization, the Forsyth County Bee Club. According to County Farm Demonstrator Bruce Anderson it is an enthusiastic young club that expects to grow and produce some real results. One of their rules requires that "members must keep records of their colonies—that is, cost of colony, time of swarming, cost of materials, and amount of surplus secured." Not a bad rule, either.

In a letter recently received the writer remarked that the name at the head of this page attached to my verses did not of itself signify either Miss or Mrs. Well, if any one has the time and patience to read all the way through the following verse, that point may be made clear!

AN OLD-FASHIONED DRIVE.

My sweetheart took me out for a drive
On a day like a dream come true.
We went right into the heart of the hills
Where the sunlight slanted through;
Where old rail fences and low rock walls
Were hung with ivy and moss,
And a pebbly stream sang low in its dream
Till we waked it, splashing across.
The road was a tangle of sun and shade
Under boughs of sunlit green,
With the hazy hue of the distant blue
Where the far hills rose between.

The dogwood-trees were white with flower,
And a sudden sweetness blew
Where the delicate blossoming locust swung
Or the honeysuckle grew.
The woodpeckers tapped and the brown thrush sang,
And, darting along by the fence,
Were bluebirds and wrens and orioles
Exchanging their compliments.
But sweetest of all were the mockingbirds;
They shook out their wonderful notes
With the rapture that springs from a heart that has
wings
And a song-bewildered throat.

We stopped at a home in the heart of the hills,
Where the hum of a million bees
Softened the silence with silvery sound
In the scent of the blossoming trees.
A home in the hills and the humming of bees!
A glad content and a friendly hand!
The glad content and the hum of the bees
Will linger long, for we understand.
"Did you like the drive?" my sweetheart asked;
"As well as our other drives?" urged he.
"This drive was the best," my heart confessed,
"Of all our drives since you married me."

NOTES FROM CANADA.—Continued from page 352.

a big difference, no doubt. During real cold weather I sometimes wish that I might spend the winters in a more balmy clime; yet, after all, no country has a monopoly of the good or bad features, and things are pretty evenly divided up, all things considered. During the beautiful cold and clear days of our past winter, to have mentioned going south to our young folks enjoying skating and other winter sports would only have brought a smile of contempt from them; and it is a fact that they prefer the winter season to the summer. While we might desire to be tinkering with the bees early in the season, yet the conditions forbid that here, and at the same time make it

unnecessary to do any work at that time. Seemingly the bees get ready for the honey-flow just the same as where the working season is longer. The moth nuisance mentioned by L. H. Scholl is a very minor evil indeed in this climate, largely because the cold weather kills all eggs that are in combs stored away, and as a result we need have no fear of our surplus combs being troubled before we want to use them the next season. And then when it comes to the summer season, needless to say we have no desire to go south then, as it certainly gets warm enough up here to suit us without going any nearer the equator.

BEEKEEPING AMONG THE ROCKIES

Wesley Foster, Boulder, Colorado.

Early in February bees were wintering almost perfectly; but March was a cold and stormy month, and colonies are weaker at present than two months ago. The weather has now warmed up, and most colonies are breeding well.

The average colony has brood in three combs. It is still early; and with good weather breeding will go on at a rapid rate. We have had a great deal of spring moisture, and the precipitation so far this year is an inch above normal. The snow in the mountains is short, and August will probably be a dry month unless we have rains, which is not likely. Losses have been reported to me from western Colorado as arising from granulated honey in the hives.

MONTANA FAILS TO SECURE APIARY INSPECTION.

Word has just reached me that the apiary-inspection bill before the Montana legislature was smothered in committee. This bill was drawn by the legislative committee of the Montana Beekeepers' Association, and with the help of Prof. R. A. Cooley, State Entomologist. It was introduced rather late; but the opposition, it seems, came from a small number of beekeepers who have the idea that it is more profitable to let foul brood clean out the small farmer beekeeper, and leave the territory free for the specialist.

HOW FAR BEES WILL FLY AND GATHER HONEY.

My experience seems to show that bees will not go three miles and gather nectar successfully from alfalfa. I have had apiaries less than three miles apart that would vary from no surplus to 60 lbs. of comb honey—a mesa a mile wide intervening. I have seen a hailstorm extend its ravages several miles in extent and a mile wide, and reduce the surplus of apiaries in its path by 50 per cent. I do not believe bees work successfully on alfalfa much more than a mile and a half. The reason probably is that bees have to work a long time to get a load; and if they have to fly too far from home they decide it is too much sugar for a cent.

SPRAYING-COVER-CROPS AMENDMENT LOST.

The amendment to the Colorado apiary-inspection law failed of passage. This

amendment provided for cutting of cover crops that might be in bloom before orchards in which they grow are sprayed. There was opposition to the bill among some fruit-growers. It is possible that, with more work, the bill might have been passed. All that now can be done is to carry on a campaign of education and publicity. Every county association should have a committee to look after the interests of the beekeepers and confer with the fruit-growers, so that no needless losses may be sustained. By careful selection of tactful beekeepers much good can be done and damage averted if work is begun in time.

Losses will undoubtedly be suffered this year, and the support and co-operation of all beekeepers should go to the beekeepers located in the commercial-fruit districts.

Many beekeepers will doubtless help their fruit-growing neighbors cut the clover, and others will only need to confer with the fruitmen to avert the trouble.

EXPERIENCE AND TRAINING NECESSARY FOR INSPECTORS.

I have seen a few cases where inspectors have caused unnecessary loss by their zeal. Let me say that an inspector must be zealous, but in some cases the cure has been worse than the disease. Inspectors who have had ten years' experience with foul brood are not unduly drastic in their orders. Burning up hives and combs of all diseased colonies is unnecessary unless the owner refuses to care for the treated colonies. Radically different tactics should be used if foul brood is found in a new and uninfected district than if it is found in an old infected area. Severe measures are defensible to protect clean districts. I have known cases where beekeepers have been fined, and their infected hives and combs burned, because they had not treated diseased material that was stored in a safe place where bees could not get at it. A reasonable length of time should be given to clean up, and the owner should be allowed to save the hives and wax if he is competent. An officious inspector is not a credit to the beekeeping fraternity. It would be a fine thing if every inspector could be given a month of coaching before taking up his duties.

If some method of federal inspection for all interstate shipments of bees could be secured it would help control the spread of bee diseases.

CONVERSATIONS WITH DOOLITTLE

At Borodino, New York.

THERE IS A DIFFERENCE IN MEN.

"Say, Doolittle, why is it that you always write so rosy about beekeeping? Even when you tell us about the hard work and stings which come to the man keeping bees, you do it in a way that makes

the apiary look enchanted. I have been fairly successful, and was quite encouraged until I ran across an old beekeeper a few days ago who gave me such a sorrowful account of his life that I have been wondering if I had not made a mistake in starting with bees at all."

Well, now, if I have put too rosy a side to the world in my writings, I am sorry. I have tried hard to keep myself down to just what I have done, and to my results. Perhaps I should have given only the financial side; but when the fun side looms up higher above the horizon than the financial, it is hard for me to pin myself down to the sordid idea of dollars and cents only. Two or three years after I started in beekeeping I became acquainted with two men who had kept bees for a score or more of years. One of them was as sour as a pickle. They told me this man had opportunities when he was younger, but he never seemed to take advantage of them. Since he took up one hive after another till there were hardly two hives of the same pattern in his apiary, so that when he wished to exchange frames of brood or honey from one colony to another, nothing would fit; and when it came to supers they could not be exchanged, nor would they fit more than one or two of any of the hives. When swarms came out he had nothing for them; and while he was working to get things ready the swarm would leave for parts unknown. The grass and weeds grew up in front of the hive entrances. Covers, bottom-boards, and hives were thrown down and left as they were thrown. In one corner of the beeyard there was a pile of hives, supers, and frames of comb that had been there ten years or more when I first visited him. The bottom of the pile was pretty well rotted, and the combs eaten with moth-worms, while more was being added to the top each year.

The other man was very different. His hives were all of one pattern. All of his covers, bottom-boards, and supers were a perfect fit on the hives or on each other when stored away in the bee-house. When in use his hives always stood level while the combs were being built so that all were true

in the frames or the sections. Each row of hives was as straight as a line could make them. Did the action of frost during the winter cause the stands to get "out of wind," they were all straightened up during the early days of spring. At the same time every thing was picked up, so that the grass and weeds could be cut and kept in check later when the bees were at work on the white-clover and basswood bloom. And when doing this he was always whistling or singing, to the enjoyment of himself and all who saw or heard him.

When I asked him if he did not get tired of the almost endless round of work necessary to keep his apiary in apple-pie order, he smiled and said, "Certainly not. It has been a pleasure to me all these years, because I find my chief joy in the apiary."

When I questioned him regarding the financial side of the matter he replied, "That is only secondary. What I mean is that the man who takes pleasure and joy in the apiary, or any undertaking in life, for that matter, puts enough spirit into it so that, barring accidents, a financial success is certain to follow." Right here hinges the difference between the successful beekeeper and the unsuccessful one. The former takes the stings and the hard work with a smile on his face as he looks forward toward the evening tide of life, when upon what he has accomplished shall be written "Well done." In the meantime the other grows bitter because he has used no personality in any of his undertakings. The latter has the same chance offered him in the beginning, but looks only on the financial side, and does every thing in a slipshod way. In other words, he can't find the joy and pleasure.

In my farming days I remember a neighbor who whistled and sang as he followed the plow and harrow, even when he was so tired that he could hardly put one foot before the other as quitting time drew near. Sometimes he would stop a moment to look at the straight furrows which had been made during the day, and then across the valley to the farmhouse among the blooming apple-trees, where satisfaction would come from the rest during the night. It is the joy and pleasure in the doing which lifts the man and his work out of the drudgery so many are complaining about. You can not find any great man who did not find his greatness in the joy in his work.

GENERAL CORRESPONDENCE

SOME ADVENTURES IN REQUEENING 200 COLONIES

BY FLORA M'INTYRE

Last summer we decided to requeen all colonies with two-year-old queens, and all that had shown any trace of European foul brood in the spring, making about two hundred in all. The next question was, "Who will do the work?" Mr. Hicks, who had had the bees on shares, was to give them up at the end of the season, and did not want the job. I said to the Mother, "We can do it ourselves. You and the School Girl can do the work with some unskilled help, perhaps. I will be Chief Adviser, and perhaps the Teacher will help." And so it came about that the Mother and I arrived at the ranch June 17, with a camp outfit and an A B C and X Y Z in case several years away from the bees should make us a little uncertain on some points.

The Teacher arrived next day; and on the 19th, work with the bees began. Mr. Hicks marked in the book the three best colonies in the apiary, from all of which we took larvæ for queen-rearing in the course of the summer. These colonies had resisted foul brood, and gathered several superfuls of honey each this year, when the apiary as a whole produced only about half a crop. Six colonies (which proved later to be too many) were made queenless for cell-starters, and two were discovered to be superseding. So we started two sticks of cells right away, and began our "cells started" record with

6—19 C 25 fr. D4

6—19 F 20 fr. D4

The fourth colony in row D was the breeder used. The Mother did the work in the apiary, while I, having had more experience with queen-rearing, and being too much of an invalid to work among the bees, gave directions and transferred the larvæ. No transferring-tools were to be located that first day; but we were too eager for the work to wait, so we improvised. A short search brought to light a chicken feather. This was quickly cut into the desired shape for transferring; and for handling the royal jelly the ever-useful hairpin answered very well. Later we purchased an ear-spoon. Wooden and wax cell-cups and cell-protectors were included in our baggage. The Teacher cut out the lower half of two combs, and drove two small nails into the end-bars, just far enough

Ready for work.

below the comb that remained to hold a shortened bottom-bar in place as in the illustration. On two bottom-bars shortened to fit into a frame she placed wooden cell cups and pressed a little wax-cup into each. I put in the royal jelly and the larvæ, placed the sticks in the combs and wrapped all up carefully to keep the temperature even on the way to the hives. The Mother put a frame each in the brood - chambers of C25 and F20, and the first day's work was finished.

In August, when the job was nearly done, we felt that we had proven that it could be done by one woman who would not for a moment be called strong. After we had been on the ranch about two weeks she and the Mother worked together with half a day's help from Mr. Hicks in killing queens. Then the Teacher and the Mother left the ranch, and after that the School Girl did the campwork, some irrigating, and the beework alone under my directions. Of course she could not give the bees full time. So I think we averaged one woman in the bees for about two months.

The Teacher is one of those benighted persons who do not like bees. She worked for one day with the Mother killing queens; but her motions were jerky, and that made the bees insufferably cross. The next day she started work on her own hook; but after opening three hives and finding only one queen she left the apiary in great haste, followed by a cloud of angry bees. After that she devoted herself to the campwork, to getting the Mother's wardrobe ready for her vacation trip, and to irrigating the young orange-trees. Referring to the last-named work, which was done with a hoe and a hose, she said she did not mind "heavy plowing," but could not stand beeings. The Mother, who is past fifty, and bothered with "nerves," found that her trouble was much better than when doing housework with a number of people around talking to her. The School Girl, who is in her later "teens," found the work lonesome; and so differing dispositions make the same task unbearable, pleasant, or just tolerable.

I am forbidden to tell all of our mistakes and accidents, but perhaps some of our

experiences, discoveries, and lessons learned will be of interest.

DILUTING ROYAL JELLY WITH WATER.

Mr. Hicks suggested that we dilute the royal jelly with water, mixing it thoroughly until it was thin and smooth like that which the bees give to very young larvæ. He said

Stick of cells prepared for the hive.

that he had had much greater success in getting cells accepted after he stumbled upon that idea. With our dry climate the small quantity of jelly that we put into a cell dries out a great deal during the few minutes that it takes to get a stick of cells ready and into the hive. So we followed the suggestion; and one day while preparing royal jelly I came upon some that had dried down into a hard amber-colored lump. Without giving it much thought I dropped it into the glass of water I had standing near, and went on with my work. Presently I glanced at the water, and was surprised to see that the once hard amber royal jelly had increased in size two or three times over and that it was no longer amber-colored but white. It was so soft, too, that I had some difficulty in fishing it out of the glass; and as it looked just like fresh royal jelly I stirred it in with the rest. No bad effects were observed. Several times after that I baited sticks of cells entirely with jelly that had dried hard, been softened again in water, and worked smooth. These cells were accepted exactly as well as those started with fresh jelly from an unsealed cell. We valued that discovery because we never could bring ourselves to tearing down one of our own nicely started artificial cells just for the royal jelly when the fresh article was scarce.

Once we tried transferring larvæ without royal jelly; but they looked very much dried before we got them into the hive, and,

Bees have no lack of clover near Union Center, Wis. Photographed by Mrs. G. W. Barge.

as we expected, no cells were accepted. Then I tried putting a drop of water into each cell before transferring the larvæ. The surface viscosity made it possible to float the larvæ as upon the royal jelly; but only four out of fifteen cells were accepted. I decided that there was probably too much water in the cells, so I tried another stiek with the bottoms of the cells just dampened with water; but again only four cells were accepted. About this time the School Girl decided that experimenting made too much work for the results in the way of cells accepted; and as there was now plenty of royal jelly I had no excuse for trying any thing else. We know, however, that, although the royal jelly may be made as thin as milk, clear water is not satisfactory.

VARIATION IN THE ACCEPTING OF CELLS.

We found a great variation in the enthusiasm with which different colonies accepted our artificial cells. Some would habitually accept a dozen or more out of fifteen cells, while others would, time after time, give only three or four accepted cells. We soon learned not to blame ourselves for this, but to discard the lazy ones and retain as cell-starting colonies only those that accepted a big majority of the cells given,

We found that two good cell-starting colonies and a nursery would furnish about as many cells each day as one woman should handle. It is a great temptation, during the first few days, when the work consists only of cell-starting, to prepare a great number of cells; but finding and killing queens is the hard part of the work, and the part that limits progress; and as a woman should not try to find and kill more than twenty queens in a day, many more cells than that coming on each day would be a superfluity. There is no time for starting nuclei when the work consists of killing queens, introducing cells to colonies made queenless previously and starting more cells.

Dequeening should begin about five days after the first artificial cells are started, so that a ripe cell may be introduced in a protector, and the queen hatched before any of the natural cells in the hive have produced virgins ready to make trouble. By this plan the virgin from the artificial cell hatches late enough to be accepted by the bees, and yet in time to tear down the natural cells. Since the honey-flow was becoming slack when we commenced work, we were not bothered by having swarms go off with our carefully reared virgins, as we

doubtless would have been if there had been much honey coming in.

When we had finished dequeening we began starting a few nuclei each day until we had twenty, and into these we put our surplus cells, thinking they would furnish a sufficient number of laying queens to supply those colonies which should prove to be queenless when we inspected for layers. When the School Girl began inspecting, however, we saw that we would probably need more queens than our nuclei would supply, so we began starting one stick of cells each afternoon. (We always start them in the afternoon, when the air will be warm enough to prevent chilling the larvæ.) Since these sticks as they were removed from the cell-starting colony were placed in a nursery at this stage of the work, we were using only one colony as a cell-starter.

THE NURSERY.

Our nursery consisted of a strong colony with a queen below the excluder and two combs of brood lifted into the super. Our cells were placed between these brood-combs. We put two sets of nails in our cell-starting combs so that each one could hold two sticks of cells when placed in the nursery. When the brood in the first two combs was pretty well hatched we replaced them in the brood-chamber and brought up two fresh combs of brood.

As there was little honey coming in we fed the nursery slowly in the following manner: A corner of the cloth over the super combs was turned back a little to let the bees come up to our feeder, which consisted of a quart fruit-jar turned upside

down on a saucer, with a little stick placed under the edge of the jar. Over this we placed an empty super covered with a cloth and hive-cover. We used this primitive arrangement in spite of the fact that there were several hundred regular feeders of two different types stacked up in the shop. It offered less opportunity to robbers than the outside style of feeder, and was more convenient to watch and fill than the division-board style. We fed sun-extracted honey thinned with water.

THE SMOKE METHOD OF INTRODUCING.

When the School Girl had finished inspecting and marking "L. Q.'s" and "N. L.'s" in the book she introduced all the laying queens we had in the nuclei by the much-lauded smoke method. We did not find this absolutely infallible; but even so we like it because it is so convenient, and works often enough to pay. Then she supplied all queenless colonies, including the nuclei, with cells, and we left the apiary August 19.

Some time later (Sept. 20) the Mother spent a few days at the apiary, where she inspected the colonies we left with cells, irrigated orange-trees, and doubled up to dispose of nuclei and queenless colonies. She reported a rather large percentage of "N. L.'s" where we put our last cells. It was too late in the season, I suppose, and some colonies had certainly been queenless too long. This year we hope to begin work somewhat earlier, especially if the honey-flow is short.

Ventura, Cal.

QUEEN-MATING NUCLEI

A Perfected System Developed for Economy of Operation

BY ARTHUR C. MILLER

How much does it cost to raise a queen? Possibly the professional queen-raisers have a fairly accurate idea; but those with whom I have talked have been unable to say what each part costs, or whether any one part can be reduced further.

Cell-production by several methods is fairly economical; and by one at least (the Fuller) is brought, seemingly, to the lowest terms. Introduction of virgins has also been brought to as near perfection as the business demands. Mating nuclei, however, are much more costly than they should be. The most costly are those of two or three standard frames; and the least costly, when properly used, are the "baby" nuclei.

HISTORY.

The use of small nuclei for queen-mating dates far back, just how far we may never know.

Jonas De Gelieu of Neuchatel, Switzerland, writing in 1814, after sixty odd years of beekeeping, carefully describes a nucleus box six inches square and the method of stocking and using it. He gives the credit of its origin to Schirach; and, as the latter was familiar with the usages of much earlier ages, it may date back away before his day. De Gelieu's nuclei were fitted with an assortment of five combs, some empty, some with honey, and one with brood, "especially maggots two to three days out of

FIG. 1. — Stock chambers for nucleus-hive outfit

the shell." These hives he stocked with one thousand to fifteen hundred workers, and shut them in with a "wire grating" for three days. These nuclei of De Gelieu were for raising as well as for mating the queens. We are struck by the remarkable similarity of this system with that described by Quinby in 1860.

Henry Alley appears to have been the first to operate them on a definite and extensive plan. Alley used miniature hives holding five frames, each about six inches square. These hives he stocked each season by pouring in half a pint, more or less, of bees, confining them for a day or two, and then giving them a virgin queen or a cell. But he also had a "stock" hive. This consisted of a body which held ten of the little frames. Three or four such bodies tiered up would hold a fair-sized colony and furnish him with brood for the little hives. But these stock hives were of awkward proportions. He could not successfully winter them out of doors, and even indoors the results were often a disappointment to him. So he depended mostly on bees shaken from combs for stocking his small nuclei. He recognized the value of a "stock" hive, but failed to make one successful.

Later E. L. Pratt, a pupil of Alley's, brought out a nucleus very much smaller than Alley's, and more thoroughly system-

atized, in that the frames were designed so several would fit within a regular L. frame, and were stocked with comb, brood, and stores in standard colonies. This made comparatively easy the seasonable stocking of the nuclei and the economical disposition of brood and bees at the close of the season.

Alley's nuclei were a great economy over the use of standard frames, and Pratt's were an advance over Alley's, but both called for an almost constant oversight. Alley's nucleus box and frames were substantial and easily handled, but he lacked a satisfactory "stock" hive. Pratt's "stock" system was practical, but his nucleus box and frames were frail.

The principal drawback to Pratt's system of using the little frames inside of standard ones for stocking was the time and trouble of adjusting or removing them, which was much aggravated by accumulation of propolis. Also at first there was much breakage of the small frames, but later they were made stronger.

Both Alley's and Pratt's nuclei needed almost daily attention, and each had to be alert that the little colonies did not get overpopulous and swarm. Taken all together, the troubles with the little nuclei are so many that the average honey-producer prefers to use nuclei of two or more full-sized combs each. And I understand that the

FIG. 2.—Slatted partition used in stock-chamber and nucleus hive, showing inside.

commercial queen-raisers who use the "baby" nuclei have more or less trouble with them.

Baby nuclei properly formed are a real economy so far as bees are concerned, for one good colony will make twenty-five to fifty, whereas it would make but about five if on standard frames. Besides cost of bees there is the difference in cost of equipment—an item of no small consequence. As an offset against saving in bees and equipment in using baby nuclei is the matter of labor in watching over and caring for them. Which is the cheaper?

I puzzled over that question for a long time. I wanted to use the little hives because of the economies, but I *must* be able to leave the little colonies to their own devices for days or a week, or even more at a time, and that seemed to be impossible. Little by little, however, I found out the laws underlying their behavior; and when I finally found that the "moist" sugars sufficed as food for them, as well as for full colonies, I had only to devise a suitable "stock" hive to have a complete system economical in every detail. For some years I have had such a stock hive and system, and I believe that I am warranted in considering it as low in first cost, and as economical in labor and attention, as anything yet described. I am not a commercial queen-raiser; and while the system is perfectly adapted to their use, I worked it out from the standpoint of the commercial honey-producer.

The basis was Alley's nucleus, which was slightly changed in dimensions to enable me to use the frames in standard fittings. The nucleus hive used by Alley was heavier than I thought necessary. The syrup-feeder arrangement I did not use, and the flat cover would not stay put without a weight or fastening. Also, in my location the cold nights and fogs called for a warmer hive, one better protected from external changes, and one in which a small lot of bees could keep things as they desired, as well as a large lot in a big hive. To accomplish this, and at the same time have it light and convenient, as well as inexpensive, was not at first easy; but the goal was finally reached, and the complete outfit and system is here described.

THE EQUIPMENT.

First, the "stock" hive. The floor is standard. The "bodies" are standard deep supers with rabbets along the long sides instead of along the ends (*i. e.*, supers for crossway frames). The covers are a standard super cover and a telescope cover. One to five "bodies" are used for each "stock" hive.

These "bodies" are arranged inside in the following manner: The rabbets are cut deep enough for metal rabbets to be used. Longitudinally through the center is hung a slat-filled frame having metal rabbets along each top edge. This frame is as long as a standard brood or super frame, and the tin rabbets are as long as the inside of the "body." Into the inside of the ends of the

body staples are driven, and the tin rabbets of the frame hang on these. The result is a slotted partition down the middle of the body, and the rabbets on it level with those along the sides, and the bottom of the partition is flush with the bottom edge of the body. The partition is $\frac{7}{8}$ inch wide. The top slat is $\frac{1}{2}$ inch thick, and the others are $\frac{1}{4}$ inch, and spaced $\frac{1}{4}$ inch apart. To prevent the partition from swinging, a staple is driven into the bottom of each end. They are allowed to project so they bind against the body ends. All of this will be plain by consulting Figs. 1 and 2.

The little frames, which are $5\frac{1}{2}$ inches deep by $6\frac{1}{4}$ long, have short ends to top-bars; are end-staple spaced, and made of stock $\frac{7}{8}$ inch wide. Top and end bars are $\frac{3}{8}$ inch thick, and bottom-bar is $\frac{1}{4}$ inch thick. If I were making new ones I would use stock one inch wide. Twelve of these little frames go on each side of the partition and spacing, and supports are such that trouble from propolizing is reduced to a minimum.

Queen-mating nucleus hive showing outer and inner cover (a corner of the slatted partition used in the stock hive showing in the background.)

The nucleus box is shown in Fig. 3. It consists of two boxes made of stock $\frac{1}{4}$ inch thick, the outer box being $8\frac{1}{2}$ inches square by $7\frac{7}{8}$ inches high outside measure. The inner box is $7\frac{3}{8}$ inches square by $5\frac{5}{8}$ inches high, outside measure. Between the two at bottom, and around all sides, is a double thickness of wool felting. Metal rabbets close the top of the felt-filled space on two sides, and strips of wood are similarly used on the other two sides. The entrance is a half-inch hole bored on a slight upward slant, the under side of the inner end being flush with upper surface of the floor of the

inner box. A tin tube lines the entrance passage, preventing air or moisture getting in between the boxes at that point. Frames hang side to the entrance. A strip of folded felt one inch wide is nailed about the upper edge of the box as shown, and this serves to make the cover virtually air-tight, and prevents its blowing off. The inner cover is a square board $\frac{1}{4}$ inch thick, the upper surface felt-covered and cleated. The outer cover is of good heavy tin, with hemmed edges, and painted white inside and out. It is two inches deep. All of the felt is lightly oiled with thin mineral machine oil to prevent the depredations of moths and to lessen the effect of moisture.

The feeders for the nucleus hives are simply miniatures of the division-board type. One of these filled with soft sugar is used in each nucleus. A feederful will usually last through the season, the amount consumed varying with the supply of nectar secured. Any of the fondant sugar candies will do as well; but where a satisfactory moist sugar can be bought it is easier to use and is cheaper.

Except for the white tin covers, everything pertaining to queen-raising is painted a light slate color. This is to facilitate the work—no guessing as to what is inside a “super” of that color, and no wondering where a “stock chamber” was put, if it was set on some colony for stocking with bees or honey.

The nucleus boxes cost 18 cents per pair, including inner cover; rabbets and tube for entrance 2 cents for each hive; tin covers, 16 cents each; cleats, etc., 3 cents per hive. Felt was scrap I got from a mill, and I cannot tell what it would cost, but probably an equivalent could be bought for not to exceed 5 cents per hive. This makes the total cost of a nucleus hive without feeder 44 cents. Paint and labor is extra. Frames cost 2 cents each. Any one trying such an outfit, and working from my figures, should be sure to use supers 16 inches wide. If supers $16\frac{1}{4}$ inches wide are used, the slatted partitions will need to be $\frac{1}{4}$ inch thicker.

OPERATION.

The use of this equipment is simplicity

itself. The "stock" chambers are filled with bees either by running in a natural or forced swarm, or else a chamber is set over or under a full colony until the foundation in the little frames is drawn out and filled with brood and stores. Then they are placed on a stand of their own and given a queen. A light-colored queen of quiet ways is to be desired, as it greatly lessens the chance of taking the queen when making up nuclei. And when the system is thoroughly established it will be found worth while to keep these stock hives headed by queens whose offspring are quiet, good protectors of home, and given to minding their own business.

Two stock chambers will hold a strong colony. In the spring additional chambers are added, and the colony allowed to occupy all the room it will. Bees winter as well in these hives as they do in standard hives. As the chambers are of regulation size, they will take regular honey-boards, etc., so that colonies in them, if not needed for nuclei, can be supered and manipulated the same as any colony.

When a nucleus is wanted, a "stock" hive is opened, two of the little combs of brood, stores, and bees are taken and put into a nucleus hive, together with a sugar-feeder, the covers put on, entrance plugged with a leaf, and the hive set where it is to stay. A cell or a virgin queen is given later. The vacancy left in the stock hive is filled with frames of comb or foundation. Nearly a whole stock colony may be used thus, leaving only two combs of brood and bees with the queen. In such a case, the stock hive is reduced to one chamber, and the entrance contracted. The field bees which return will give it a good start in rebuilding.

If a nucleus gets a little weak, one of its combs is exchanged for one of brood and bees from the stock hive; or if, perchance, one gets too populous, a comb with adhering bees is taken from it and exchanged for a comb of stores from the stock hive or for a dry comb. In this shifting of combs, it is only necessary to have a care what is used, and, when a virgin is in the nucleus, to observe the necessary precautions, whether standard frame or baby nuclei are used. In making any nuclei some pains must be used to get a fair balance of brood and bees, and this is easier with a lot of small combs to select from than with a few large ones.

Two combs of brood and bees are all that are used in a nucleus, although occasionally a third comb may be put in, but not often, and never more than that. The little hives will hold five frames; but two or three and

the feeder are the limit of what are used. The occupied combs are next to the entrance, the feeder behind them and the vacant space behind that. Thus arranged, the little colonies will take care of themselves for one to two weeks at a time and not offer to swarm out. Fill the hive full of combs, even if one or more of them are empty, and swarming out may become a nuisance. I do not know why. Recently a man in Texas confirmed this.

It will be noticed that the brood is placed next to the entrance, and the vacant space is at the back. This is the opposite of the principle for prevention of swarming as laid down by Langstroth, and later emphasized by Simmins, that the vacant space should be between the brood and the entrance. But with these nuclei we are not dealing with a normal swarming impulse, but with something having to do with the bees' ability to protect their entrance, and at the same time have freedom from any sense of crowding. Be the "reasons" or causes what they may, thus arranged they "stay put," while differently they may not.

So long as these little colonies have room and food, they work on as normally and seemingly as cheerfully as a full-sized colony, even to the extent of raising a good queen now and then—not that they are ordinarily permitted to do such a thing, but once in a while one is overlooked after being dequeened, and then they raise a queen. I have seen as fine a queen raised by a couple of hundred bees in one of these little nuclei as was ever raised by a full colony. Of course, the conditions as to nurses, food supply, temperature, etc., were all just right. The temperature in hives made as described is easily controlled by a very small number of bees; they readily protect the half-inch entrance, and the sugar stores attract no robbers, except the ants. And ants, by the way, are sometimes a nuisance when sugar or candy food is used; but setting the nucleus on a piece of tarred paper a little larger than the hive usually prevents their attack. If once started they may continue despite the application of the paper, and then I have found it necessary to lift the combs and bees into a fresh hive, giving a fresh feeder; and with a brush and any of the creosote compounds, draw a line on the paper around the hive. That gets rid of the ants in the hive, and those outside seldom set up a new line of march across the creosoted strip. Where hives are on stands, treating the legs with the creosote compound will usually suffice, provided the ants are gotten out of the hives first.

Two minor items are worth mentioning, as they add to the general convenience of the operator. The floor of the inner box is painted with enamel white paint, for two reasons: First, if it gets sticky it is easy to wipe or rinse clean; second, if the young queen is timid, and runs from the combs to the floor, she is easily seen. When holding any nuclei very late into the fall for mating choice queens to selected drones, the nuclei are made quite strong, as baby nuclei go, by shaking in young bees and then a piece of wool felt is laid on top of the frames and under the regular inner cover of wood—seemingly small matters these, but some small things save many large troubles and losses.

Toward the end of the season, when the number of nuclei needed is diminishing, the surplus ones are united with any stock hive by the simple process of putting on to the latter an empty stock chamber and hanging the combs and bees from the nuclei into it, observing only the common precautions used in uniting bees. As such wholesale uniting is done when colonies are contracting, the bees will leave the upper chambers soon after the last of the brood emerges, and then all chambers not needed are removed and the colony is supplied with stores if necessary. Thereafter it is treated and wintered as are colonies in standard hives.

Providence, R. I.

PRACTICAL METHODS OF QUEEN-MATING FOR THE BEEKEEPER

BY E. F. ATWATER

In rearing queens for our own use we have for several years used about 100 nuclei, containing the little frames $5\frac{5}{8} \times 8$. By proper use they certainly will give the best of results. For some years we would fit three of these little frames into one standard frame, to get them stocked with brood or honey, or to get combs built.

A few years ago, however, I found that a shallow extracting-super, 6 inches deep, as shown in the cut, with a board across the

inside, we made a super or brood-body that would hold twenty of the little frames. The partition is made of two 7-16-inch boards with a folded tin projection at the top.

Since we keep one or more colonies in such hives at all times, we always have a place from which we can draw brood or honey. These prepared supers may be tiered as high as desired. Perhaps the queen would better occupy both parts of each section if the division-board were of slats, bee-spaced apart, as in the Aspinwall hive.

When we wish to start our nuclei, if we have not enough combs containing some honey reserved from the previous year, we take several of these supers containing twenty of the little combs (even spaced so that each contains 22) and put one on each of several strong colonies.

Under such colonies we put either an Alexander feeder or one of our feeder-bottoms, and about every hour we feed these colonies until the little combs contain sufficient honey. This does not take long.

For our use we find that the little twin nucleus boxes are not the

A shallow extracting super can be converted into a handy brood body containing twenty little frames.

A smaller body can be constructed on the same principle.
Note the tin division-board.

best. So we make other boxes similar to the first, except that each side has space for four frames, and a tin division-board in the middle has canvas tacked to its top-bar for covering each side. A ventilator, as shown, is provided for each compartment. The little button contains a bit of perforated zinc, which may be turned to cover the entrance, when desired. The lids are double, air-spaced, covered with metal, and painted white.

When we start our nuclei we bring bees in swarm-boxes from outyards and put them in a cool place. Into each compartment of the nucleus hive, one of the combs of honey is placed; and next to it, if we have it, an empty comb; or, lacking this, a frame with a narrow starter.

In four to six hours after confining the bees we smoke them in one of the swarm-boxes with tobacco smoke, and then dip a large cupful into each compartment, cover

with the quilt, close the entrance with the button, open the ventilator, and put on the lid.

When all are filled, we run a virgin into each compartment, following her with a little tobacco smoke. Virgins of any age are usually accepted.

That evening the little boxes are set in their places. Early next morning the entrances are opened, or else at time of forming they are set in their places in the shade, and the entrances filled with candy, so that they will release themselves at pleasure.

The extensive producer can not watch his nuclei as closely as necessary with the little two-frame compartments usually employed. With ours, however, each containing room for four frames, one has only to add a frame with a starter to the stronger ones, when they will fill it with fine worker comb as soon as their queen commences to lay.

If the queen is not needed at once, another frame with starter will keep them busy for several days more. Then when brood begins to hatch, they may be divided by taking the laying queens and a frame of brood and bees, and putting them in another nucleus hive. The little colony on the old stand will gladly accept another virgin in three days.

Meridian, Idaho.

Each compartment has its screened ventilator.

A PHOTOGRAPHIC INTERVIEW WITH THE BEE-MOTH

BY CHARLES Y. HAKE

The bee-moth I consider the quickest in action and the most destructive pest of the honeybee. We can be thankful for carbon disulphide, quicker in action than even the bee-moth, and sure death to the enemy.

This case of bee-moth in my apiary does not show any carelessness on my part, but was merely a snare or trap to draw most of the moth to one particular place. I placed five brood-frames with old comb in

a box hive at one end of the yard, leaving the entrance wide open for whatever would go in. After leaving it in this condition for eight days I made an examination, and the results are shown in the photographs.

One of the pictures represents a regular brood-frame spun with bee-moth web and cocoons in the center containing live moth larvæ. To the right of the picture is a can of carbon disulphide, the chemical I use to destroy these pests.

Cluster of bee-moth larvæ photographed exact size.

Web and cocoons in the center of a brood-frame.

Another picture represents a cluster of bee-moth larvæ photographed life size. This was fastened between a brood-frame and the end of the hive.

York, Pa.

[Some time ago, a hive of empty comb was left out by mistake at one of our out-yards. When we found it the combs were literally covered with moth larvæ. The large illustration shows the result but gives only a faint idea of the number of tiny larvæ, the moth webs, and the channels through the comb.—Ed.]

A neglected frame alive with beemoth larvae.

Ants are avoided in this Porto Rican apiary by placing the hives on iron rails. Eighteen barrels of honey from 25 colonies that were increased to 150.

A PORTO RICAN APIARY PLAN

BY J. SAMUEL COX

The one of our apiaries illustrated is shaded by banana-trees. In an open field these are very serviceable for shade, since they grow quicker than almost any other plant, and, besides, the shade can be regulated to any one's desire by cutting the leaves. Nearly all the leaves can be cut off without damaging the plant.

Our apiary here is laid out on a plan that has been mentioned somewhere in *GLEANINGS*. I think it one of the best, not only because it helps the bees and queens to locate their individual colony, but it gives to the apiary a business-like appearance. I agree with the saying, "Fine feathers do not make fine birds," but I believe in the hobby of appearance. I have seen many

come to view an apiary who would never go near enough to see the inside of a hive, and these persons have gone away elated, simply from the appearance.

Our hives here are put on iron rails such as are used on the car line. Since the entrances are placed facing each other, there is a passageway between the backs, so that a wheelbarrow can be run without interfering with the entrances. The hives are placed two by two. The closest are eight inches apart, and the next two are three feet away. This apiary was started in August, 1914, with twenty-five colonies. We have increased it to 150, and have taken 18 barrels of honey at the end of December.

Guayama, Porto Rico.

MONTANA AND WYOMING BEEKEEPING

BY WESLEY FOSTER

Bees in Montana did not do so well in 1914 as in 1913. The reason for this I have not learned. The beekeeping area is confined to the narrow irrigated valleys. There is no wide extended irrigated area such as may be found in eastern Colorado and especially northern Colorado.

The precipitation in Montana is slight, as it is in Wyoming. On January 24, about four inches of snow was on the ground, and I was told by one man at Billings that it was the most snow they had had for four years.

Alfalfa and sweet clover are the sources

of the nectar; and, while the seasons must be somewhat shorter than those further south, the days are longer and warmer than one would think for this latitude. It does not get dark until 9:30 or 10 o'clock here in the summer season, I am told, and that makes for a long growing season.

Montana is a rapidly developing state, and is destined to have a bright future. Every one seems to be doing well. Wages are high, and living also. Shaves are 25 cts. Meals at the restaurants and hotels are generally 50 cts. Nothing less than 10-cent cigars are sold, and pennies are not used in this state. I have not seen any except those I carried into Montana in my pocket.

Honey production is only in its infancy in this state, and it is bound to increase. Cattle and sheep are raised by the thousands, and the alfalfa grown finds a ready market for feeding purposes. Alfalfa will for a long time be the principal farm crop. Sugar beets, potatoes, grain, etc., are grown, but alfalfa is king. The river bottoms show that sweet clover is taking them with gratifying speed.

I mentioned that alfalfa and sweet clover furnish the surplus in Montana. Since writing this I have learned that alsike and white clover also furnish considerable honey in some of the valleys. While in Bozeman, Prof. R. A. Cooley, State Entomologist, gave me an opportunity to sample some of his comb honey which had a very pronounced flavor of alsike. Prof. Cooley is a beekeeper, and has a son he intends to train for a beekeeper.

BEEKEEPING IN WYOMING.

Four main districts in Wyoming produce honey. Since the development has not as yet been carried very far, the total honey-

Dr. Kopenhafer, president of the Montana Beekeepers' Association.

producing possibilities can hardly be estimated. Most beekeepers are probably to be found under the Shoshone project in northwestern Wyoming in the lower Big Horn Basin. Ralston and Powell are the centers. Several cars of honey are now shipped from this district. The other important district is probably around Laurer in southern and central Wyoming. Several cars of extracted honey are produced there annually. The district in which Wheatland is the center has been a honey-producing district for some time, but does not produce as white a quality of honey as formerly. One of the disadvantages of this country around Wheatland is a wind which blows all the time, ac-

Street scene in Worland, Wyoming, one of the towns in the Big Horn Basin.

Mr. Pratt's apiary, Wethersfield, Ct., where the Connecticut Beekeepers' Association met in 1914.
 Photographed by A. E. Crandall.

According to some I have talked with. This is exaggerated, but a windy country is one that should be avoided by the beekeeper if possible.

All the districts of Wyoming have more trouble in wintering than the milder climate of Colorado. If the snow falls in November in the Big Horn Basin it does not go off until spring. There are no warm chinook winds. There is but little snowfall, however, and the annual precipitation is below eight inches on the average.

The most successful beemen give their bees protection or cellar them. The loss in and around Lauder often runs as high as fifty per cent on outdoor-wintered colonies.

There are some chinook winds that take off the snow in a few hours in the lower Big Horn Basin; and I understand the winters are not so severe as they are further south. The altitude of the basin is between 3500 and 4500 feet.

Boulder, Colo.

THE VALUE OF FAIRS

BY A. E. CRANDALL

I wonder how many of the beekeepers who live near cities or towns where fairs are held take advantage of the opportunity to show their product. In this way they can get in touch with the thousands of people who annually gather at these places, and who go there to see what new things are being brought out, to talk with old friends, make new ones, and to have a good time in general. The Connecticut Beekeepers' Association is doing excellent work along this line, and many are the remarks of praise for the large bee and honey exhibit which is annually placed at the "Charter Oak Fair" in Hartford.

The fair opens on Labor Day, and affords workmen an opportunity to visit the grounds and see what is going on in the agricultural line as well as in the industrial.

I understand that, on the opening day, 70,000 people usually pass through the gate. Doesn't that seem like a fine chance to put bees and honey before the public?

Another thing, the fairs are educating people to realize the value of honey in making cakes, cookies, muffins, and in canning fruit. The culinary department at the Hartford fair provides for an exhibit of this kind, and the following prizes awarded will give some idea of what can be done along this line.

Class	PREMIUMS		
	1	2	3
18 Honey muffins.....	\$4.00	\$2.00	\$1.00
19 Cookies and gingersnaps	4.00	2.00	1.00
20 Cake	4.00	2.00	1.00
21 Canned pickles.....	4.00	2.00	1.00
22 Canned fruit	4.00	2.00	1.00

Honey to be used in preparation of above, and recipe to be attached.

A good many times one can find a store-keeper who will allow an exhibit to be placed in his window. If it is done during the summer or fall months when a frame or two of bees can be shown with a printed card such as "Find the Queen," it would serve as a means of attracting attention, and get people to thinking of honey. Otherwise they would hardly give it a passing thought. A great many regard honey as a luxury, and will use it only sparingly or in case of colds. I find a good many who use honey and lemon juice for colds, and seem to think it an unfailing remedy.

One of the illustrations shows our two children who have been sampling our favor-

Bushels of grapes grow near the hives.

ite grape, the Worden. This reminds me that I have never seen honeybees on the blossoms of the grape, but have seen plenty of bumblebees on them. Of course the bees never puncture our grapes, and we have bushels of them growing near the hives.

Berlin, Ct.

INDIANA NOTES ON SPRAYING

BY S. H. BURTON

Dr. Miller says, on page 261, that, no matter how intelligent a fruit-grower is, he will spray before bloom is gone if he is selfish enough, unless the law prevents him. He also quotes the fruit man as saying that he can't get through spraying in time unless he begins before all blossoms are gone; that to wait till all bloom is over there is danger

that some of the oldest fruit will be wormy, and that, if he sprays when two-thirds of the bloom has fallen, and kill all yet in bloom, there will still be more fruit than the trees can mature. "Me for the early spraying." Now, what reply have you?

Well, the doctor seems to put us fruit-growers all in the same class; but I for one plead "not guilty" to the above charge.

A fruit-grower who has given the matter careful and scientific study does not proceed with such feverish haste. A study of the life history of the codling moth reveals the fact that the eggs from which the larvæ develop, that cause the wormy apple, are laid on the leaves and twigs near the young fruit, and not in the blossom end of the apple, as supposed by a great many fruit-growers. Upon emerging they commence to feed at once upon the young leaves, and gradually make their way to the fruit. If arsenate of lead is applied just after the leaf-buds burst, but before the blossom-buds open, it will control 95 per cent of the codling-moth trouble, because the young worm gets its dose on the poisoned leaf before reaching the apple.

Too much emphasis has been laid on the after-blossom spray, and not enough on the importance of getting the worm before the

The second Crandall generation is as interested in bees as the first.

Cutting sweet clover with a Linder preparatory to thrashing.

apple is born. I have sprayed apples two weeks after the petals had fallen that were given the cluster-bud spray, and no difference was noted in the percentage of wormy fruit from trees that were sprayed when two-thirds of the petals had fallen. If an orchardist can afford to spray and kill one-third of the bloom, and then have more fruit left than the tree can mature, why all this haste in applying this spray? His statement doesn't bear weight. It would be just as well to let the worms have this extra one-third which will drop off, avoid

killing the bees, and save all this ripping around, trying to get the calyx cup full of poison before it closes. The fruit-grower should learn to "make haste slowly," and give more thought to just why certain operations are necessary instead of following blindly some set rule. In my opinion the cluster-bud spray, or the spray just before the blossoms burst, is worth far more in the control of codling moth and scab than any subsequent spray that can be applied.

Washington, Ind.

TWELVE HUNDRED ACRES OF SWEET CLOVER

BY K. E. HAWKINS

Over 1200 acres of sweet clover within a few miles along one road is the way Illinois farmers are responding to the work of the university and beekeepers here, who are spreading the good news around as to the value of sweet clover. This field, for it is nearly all in one field, is owned by W. P. Graham, Rochelle, Illinois; and during the past season county agricultural advisers from all over the state have organized auto trips to Rochelle to allow the farmers of Illinois to see what Graham is doing with sweet clover.

Here yields of as high as ten bushels of seed to the acre have been known. Here the clover pastures three head of cattle to the acre instead of the usual "head to the acre" of the Illinois farmer. Used for pasture, raised for seed, cut for silage, and planted to tone up the soil, clover has come into its own in this portion of the Prairie State.

Together with dozens of other farmers from this county I went to Rochelle this summer with our county soil adviser just to see these 1200 acres of clover to make sure it was a reality. A few years ago the av-

Cattle, three head to the acre, grazing on sweet clover.

erage farmer in Illinois laughed at alfalfa, not to speak of sweet clover. To-day there are hundreds of acres planted.

Mr. Graham's primary object in using the sweet clover is that it is a still better renovator of the soil than alfalfa. Beekeepers, take notice of that. When asked if he used it for grazing or seed primarily, Mr. Graham answered in the negative, saying, "Neither. I prefer it for fertilizing." Comparative tests made there in Rochelle have shown that the sweet clover, at least on that soil, renovates better, and makes the soil give greater yields of corn and potatoes following it than alfalfa.

Often it is not necessary to inoculate the soil. Where it is necessary, one may go to the roadside where sweet clover is growing, gather some of the soil from about the roots, and, after moistening the seed with a thin solution of commercial glue, sprinkle a few handfuls of the soil to the peck of seed and mix it well. The seed must be spread out carefully to allow thorough drying, else it will spoil.

When asked if he had ever had any trouble getting cattle to eat the clover, or any bad after-effects, he said he had not. The first year it may be grazed successfully, and the second, cut for the seed. It is best planted in the fall, say August. It should get enough growth in the fall rains to be six inches high for winter. Straw spread lightly over the fields aids the wintering. Three head to the acre of cattle, as the

picture shows, have been pastured there this year.

It is cut while young and tender, in the fall of the first year, and put into silos just as young and tender corn, and fed through the cold winter months just as ordinary silage. Mr. Graham says it makes very good silage. Limestone on acid soils is a necessity to get it growing, for, like alfalfa, sweet clover will not grow on a "sour" soil. The richer the land the better growth it makes, but it is unexcelled as a renovator. The picture shows the ordinary oat-binder being used to cut the clover, which is handled in much the same way as ordinary mammoth clover for hulling.

Mr. Graham has never kept any bees, for there are so many in the neighborhood that he believes there are enough to insure all the necessary fertilization of the blossoms. Not being a beekeeper, he had never noticed particularly that the bees worked on it, and this shows that necessity often makes one notice that which he may never have known existed. However, the yields of honey which are secured by some of the beekeepers around there point to the fact that the bees visit the blossoms very much, and are more of a necessity than Mr. Graham had thought. It is conjectured that the wind fertilizes to a great extent where so many acres stand side by side, as in the case of corn, while solitary plants along the roadside would not bear seed unless visited by bees continually.

Plainfield, Ill.

OFF YEARS IN SWEET-CLOVER NECTAR

BY VIRGIL WEAVER

Sweet clover is a great honey-plant under favorable conditions. It will yield as fast as almost any of the clovers, but it will not provide nectar every year. I was led to believe that this was the case, so in 1913 I shipped 131 colonies of bees to Pendleton County on the first of July. Pendleton County beekeepers told me that the last of June and the first half of July is the best time for white sweet clover. The result was that they never stored a pound of honey, and had to be fed through August and September. Out of the 131 colonies, 28 of them wintered.

As the 1913 drouth killed all prospects for white clover for 1914 in Madison County (where I formerly lived) I shipped all my bees in Pendleton County for 1914. Here is the result. Until May the rain was plentiful, May 8 giving one inch. By May 15 the yellow was in full bloom, and by June 1 the bloom was gone and not a pound of honey had been gathered. From June 1 to 6 we had $2\frac{1}{4}$ inches of rain on the eastern side of the county, and from $2\frac{1}{4}$ to 7 inches on the west side of the county—a regular soaker. White sweet clover was in full bloom by June 15.

The record of the colony on scales will tell the result better than I can. Here is what it says:

May 20, weight $58\frac{1}{2}$ lbs.; July 10, $63\frac{3}{4}$ lbs. This was a No. 1 colony. I got through the season without any feeding. Buckberry did the work and not sweet clover. Buckberry gave us a slow honey-flow from Aug. 1 to September 15, ample for the need of the bees.

Sweet clover is one of the very best forage plants, and provides wonderful pasturage and excellent hay. Its value as a soil renovator is unequaled. This county of Pendleton fifteen years ago was a barren waste. It had been "tobaccoed" to death. By some means this plant became introduced, and for long it was fought as a weed. Finally the farmers began to realize its value, and, to make a long story short, land which was worth from five to ten dollars per acre at that time is now realizing from forty to sixty dollars per acre. There is another comparison. At that time the farmers were abandoning their farms and seeking employment in the cities. They did not have sufficient means to buy suitable clothing for themselves. At present there is on deposit in the various banks of Pendleton County money aggregating over \$100 per capita, most of which belongs to the farmers.

But don't get it into your head that sweet clover does not have to have moisture to make it yield honey. I believe that about one year in three it will yield a good lot of honey. This will help out white clover here, as that yields about one year in three also. So the two together make a good team.

Alsike clover is the surest yielder of honey of all the clovers. I saw this demonstrated this year. Fifty colonies of bees in reach of fifty acres of alsike stored thirty sections per colony, while those in reach of a larger area of sweet clover stored nothing. It takes two years to work the combination on honey production, one year to grow the plants, one year to grow the seed. We are hoping for something better this year; so, come down and see us.

Falmouth, Ky.

SOME SEED PROBLEMS OF SWEET CLOVER.

[Can sweet clover be gotten rid of after a crop has been grown, and small grains sown the next year? This is a question which has worried farmers wherever the plant is being introduced. One reported that he had planted wheat the spring following a crop of sweet clover in the same field, and that the clover had choked out the wheat. The experience is unusual, to say the least.

The best crop to put in immediately following sweet clover is corn. The effect of the sweet clover will be noticed only in increased growth of the corn, sometimes as much as twenty bushels heavier than in land not previously planted in corn. Sometimes corn is grown two years in succession, and then followed by wheat. No trouble with smothering is ever reported. The farmer need fear no difficulty in getting rid of sweet clover after he has once sown it. The fact that the plant grows abundantly along the roadsides, and seldom appears in cultivated fields, is evidence that it can be easily destroyed if necessary.

Another point on which there is question is the amount of sweet-clover seed to be mixed with oats in seeding them together. Some sow ten pounds to the acre, others as much as twenty. A good average is fifteen. Care must be taken in mixing the seed in the drill, and in not having so much in at once that the clover will work down under the oats in the drill-box. This would mean uneven proportions in the field. With care the seeding can be made even. Hulled sweet clover is more satisfactory in such a mixture, since some of the unhulled is not likely to come up the first year.—Ed.]

THE ALEXANDER METHOD IN A CLOVER LOCATION; SOME FURTHER PARTICULARS AND A REPLY TO DR. MILLER

BY IONA FOWLS

In *Stray Straws*, April 1, 1915, Dr. C. C. Miller seems surprised at my statement that the swarming tendency would very rapidly develop into a mania if we put the queenless colony right on top with nothing but the honey-board between; and he thinks Mr. Alexander and himself would have discovered it if that were true. He then asks, "What can make the difference?" Well, the difference is that Alexander's queenless colony and our queenless colony are under quite different conditions. He took bees that had not begun swarming. Ours may be at quite an advanced stage.

Mr. Alexander's plan, according to his own words, was to be put in operation "when your colonies are nearly full enough to swarm naturally." And later he says, "I find that nearly all who have made a failure of the method have taken colonies that had already made some preparation for swarming by having eggs or larvæ in their queen-cells." Now, our plan is applied at the very stage that he considers liable to cause failure under his method. In fact, we even take bees that have *capped queen-cells* present; and, please notice, we leave all the cells except the capped ones. Moreover, his queenless colony is left but five days, while ours is left seven or eight. Therefore his queen-cells would have larvæ no more than one or two days old, while ours might be ready to hatch. And yet I notice that, in dealing with these bees that have not even begun raising cells, Mr. Alexander says, "Leave them in this way five days, then . . . destroy any larvæ you may find in the queen-cells . . . for they frequently start the rearing of queens above the excluder. If so, you had better separate them at once."

Why separate them "at once"? Because he knew that some of the cell-builders, if placed so close to the lower hive that only a honey-board intervened, would very likely pass through into the lower hive and also start cells there, and thus the swarming idea would become firmly fixed. Well, if he

recognized such a danger when cells were but five days old, how much safety would he have felt with cells at all stages from one to sixteen days old?

Our idea is to get those cell-builders further away from the queen, so that the bees of the lower story will not begin raising cells; for our experience has been that, with such advanced cells above, the lower colony will very soon catch the swarming fever unless the two stories are separated by inserting supers; and the further the brood is isolated from the queen, the more queenless the bees of the upper story seem to feel, and the less likely is it that the presence of cells above will cause swarming to be started below. Consequently we put two or three supers between; and we find, so far as isolation is concerned, it has about the same effect as moving the upper story to a new stand. However, it is vastly better, for we not only keep the bees at work, but also save the larvæ.

Evidently, in the March 15th number I did not make myself very clear, for I had no idea of criticising the Alexander method. If one desires increase, and has his bees all in one apiary, as Alexander had, it would probably be difficult to find a better plan than his. But for the sake of those who have several outyards, and also wish to keep down the increase, I thought I would like to clear up any points that might arise concerning a plan that has proved so helpful for us.

Father could not remember where he first obtained the idea of the plan. Imagine my surprise this morning when I finally located the suggestion in the first paragraph of an article entitled, "Do Queen-cells above a Comb-honey Super Bring on Swarming?" by Dr. C. C. Miller, Aug. 15, 1911; and to think that Dr. Miller is to blame for it! Well, never mind. The plan works out beautifully, and we are just as much obliged for it as though he had written it for our special benefit.

Oberlin, Ohio.

NEW BRUNSWICK CONVENTION

BY H. B. DUROST

A meeting of the directors of the New Brunswick Beekeepers' Association at Fred-erieton on March 9 was marked by a good attendance, interest, and enthusiasm. A

number of most important subjects, bearing directly on the interests of those keeping bees in the province, were dealt with in a businesslike manner.

The subject of a law to prevent the introduction and spread of contagious bee diseases was thoroughly discussed. All were agreed that the time was ripe for the beekeepers of the province to ask for such a law; and it was finally decided that the association petition the legislature, now in session, to take action in the matter. In view of the fact that the province is practically free from the dread disease "foul brood," it was felt that a law to prevent its introduction would best suit our needs.

It was finally agreed that a law be asked for, modeled after that of Ontario, with a clause such as is found in the British Columbia act to give the Minister of Agriculture power to order bees coming into the province on their comb to be placed in quarantine for a fixed period. It was stated that the disease probably did exist in the province at a few isolated points. In order to prevent its spread, and to find and stamp it out if it did exist, it was decided that a clause should be inserted in the law to pro-

hibit transportation companies from carrying bees on their combs from point to point in the province, except such as bore an inspector's certificate of recent inspection.

It has been recognized that one of the greatest drawbacks to an increased interest in beekeeping in this province was a lack of easy access to a source of good beekeepers' supplies. Last season the association handled supplies at cost for its members through its secretary. Objection to this was raised, so a new plan was adopted. This season the county secretaries or directors have been authorized to collect and forward to the president all orders for supplies from all members in their respective counties. The president will combine these orders and forward them to the supply concern offering greatest inducements. The goods will be shipped direct to the parties ordering.

The matters of exhibition prize lists, markets, etc., were briefly discussed, and the meeting adjourned.

Woodstock, N. B.

NOTES FROM GERMANY

BY J. A. HEBERLE, B.S.

Dr. U. Kramer, a well-known author on apiculture, and one of the eminent beekeepers of Europe, died at the age of 70, on Aug. 19, at his home in Zurich. Since 1881 he has been one of the directors, and for nearly twenty years the president, of the Association of Swiss Bee-friends. Under his management, with able assistance, the association has prospered, and is probably the most perfect organization beekeepers have in any land. The association has a very ably edited bee-journal, an insurance against damages by foul brood, and a good working system of controlling the honey of such members as desire to avail themselves of it. This controlled honey is sold as "checked," the purchaser having the best assurance that he gets pure honey. Queen-rearing, select breeding to improve the native race (the black German bee), mating stations, etc., are largely due to the initiative and fostering care of Dr. U. Kramer. He succeeded in uniting and inspiring under his supervision a large number of well-trained breeders who have attracted the attention and approval of the German-speaking beekeepers of Europe. The association of German-speaking beekeepers of Switzerland is a living monument to Dr. Kramer, its former president.

POISONOUS HONEY.

The honey gathered by the bumblebee

should not be eaten, because these insects gather nectar from the poisonous *Aconitum*. Xenophon relates that his soldiers were poisoned by eating honey near Trapezund. According to investigations it is believed that the *Rhododendron ponticum* and the *Rh. flavum*, which are diligently visited by the honeybee, furnished the honey for Xenophon's soldiers. In the deserts of Uruguay the French botanist Saint Hilaire had a rather dangerous experience. On one of his excursions he found a wasp-nest on a low bush. He considered it an excellent addition to his breakfast. Very soon he and his two attendants noticed the poisonous effects. First he felt a severe pain in the stomach; then illusions troubled him. Tears ran from his eyes, succeeded by laughing-spells almost to exhaustion. Finally his sight failed him, and he thought his end was near. Two companions who came upon them toward evening succeeded in bringing him to consciousness by infusing with warm water. The next day an Indian who ate honey from a nest of the same variety of wasp, the *Lacheguana*, suffered no inconvenience at all. Probably these wasps had gathered only from non-poisonous plants.—*Kosmos*, Stuttgart.

HEATHER—ERICA VULGARIS.

This plant is in northern Germany quite important for the beekeepers. Extensive

areas are covered almost exclusively with this plant, which opens its blossoms in the first part of August. Beekeepers migrate to the heath lands from considerable distances. Entire trains loaded only with bees to be carried to these late-blooming pastures may be seen. The "Heidimkers" have from the common German black bee bred a variety called the heath-bee that differs from the original especially in its fertility and swarm impulse. In this respect it equals the Carniolan bee. Beekeepers who move to the heath want to increase as much as possible by natural swarming, and to have a high number of skeps when moving to the heath. About the middle of September the flow from the heath stops. Those skeps that the beekeeper does not want to winter are "drummed off," and the "swarms," weighing from 4 to 6 lbs., are sold from 75 cts. to \$1.10. For 12½ cts. a swarm up to 11 lbs. can be sent by mail to any part in Germany. Such swarms are put on combs, and fed sugar syrup for winter stores. The queens of such swarms are often exchanged, either in the fall or next spring. The honey from the heather is not considered first-class; and as soon as it is capped it is so viscous that it cannot

be extracted except by using a new device by which, after the comb is uncapped, something like a blunt nail is forced into each cell. Most of the heath honey is either sold as comb or chunk honey, or strained honey that has been melted with a gentle heat. It is only in the last few years that the modern hive has begun to gain favor with the Heidimker.

Besides this *Erica vulgaris*, there grows especially abundant in Karnten and Carniola the *Erica carnea* on the lower mountain sides. It blooms quite early in spring, when snow may be within a few feet. This very beautiful flower, which covers extensive areas like a crimson carpet, furnishes pollen and honey. The honey is said to be of very fine quality, but is used by the bees to build up.

I am surprised that I never see any thing mentioned about the heaths of America. Are there none in the northern or north-eastern parts? The *Erica vulgaris* grows in Germany on peat and sandy ground. The heath honey is by many considered a poor winter food, but excellent in spring to breed up rapidly.

Kempton, Bavaria, Germany.

DR. ULRICH KRAMER

BY ERNEST TSCHUDIN

The Swiss beekeepers have suffered a severe loss by the death of Dr. U. Kramer, which occurred in Zurich on the 19th of August, last year, a few days before his 70th birthday. His name is known not only in every Swiss beekeeper's home, but also far abroad, on account of his practical and scientific writings on the honeybee. He had been a lover of nature since his earliest days, and especially the bee captured his interest. While still in the state's service as teacher at the public schools at Zurich he unselfishly sacrificed most of his holidays to the cause of beekeeping, giving during this time more than 200 lectures on beekeeping, and dozens of instruction courses of several days each, all of which practically meant unpaid work in those days. Since 1895, when pensioned as teacher, he devoted all his time and strength to the promotion of beekeeping in Switzerland.

Kramer was founder of the Zurich Beekeepers' Association, 1887, and three years later he advocated the uniting of the different beekeepers' societies into a national organization, which now counts about 9500

members, belonging to 116 individual societies. Kramer had been its president for nearly twenty years. In the same year, 1884, he initiated the observation stations for studying weather and yield conditions in different regions of the country, reports to be sent in monthly. For twenty-two years Kramer acted as chief of this work, and published highly interesting reports with colored tables, which threw new light on the matter.

In the last fifteen years this institution has been also adopted in Austria and a few German states, as well as the mating-station system, another creation of Kramer. He established the first station of this kind on a small island in the lake of Zurich.

With the advance of beekeeping in the last twenty years the importation of foreign stock, especially Italian and Carniolan, had assumed great proportions. The results, however, were not always satisfactory, and Kramer, basing his statements on careful and painstaking observations, was one of the first to declare that the native "brown" bee was the race best adapted to the pecu-

DR. H. C. ULRICH KRAMER

liar climatic and other conditions of the country. At the same time he started the "pure-breeding courses," which took place yearly, and were usually attended by about a hundred beekeepers. One of his best-known writings deals with this matter (*Die Rassenzucht*). The facts prove that Kra-

mer's idea was correct. The select Swiss bee of to-day represents an excellent strain.

But Kramer was also gifted with a practical turn of mind. When, in view of the increased production, many a beekeeper was afraid that the product would go down to an unsatisfactory price, Kramer showed the way—the honey control (introduced in 1897, and directed by himself for several years) in connection with an active propaganda based on the controlled pure product. The public now usually asks for controlled honey, the purity and quality of which is warranted by the Beekeepers' Union.

As a regular contributor to the *Swiss Beekeepers' Review*, and for many years director of the bee department in the *Agricultural Journal*, and by publishing several works, partly in connection with other authorities, he had sown many a grain of wisdom that brought forth fruit. No wonder that, on various occasions, he was honored with diplomas and other distinctions, and in 1908 even a doctorate (*honoris causa*) was conferred upon him by the University of Bern in consideration of his scientific and practical merits in apiculture—the first similar honor since the days of Dzierzon.

These few notes will suffice to show the great debt of gratitude the Swiss beekeepers owe to Dr. Kramer. It seems unnecessary to say that he was a good man, a straight character, with an ideal disposition, and in his life he fully realized one of his expressions: "A right man must leave a good trace of his activity in this world."

Basel, Switzerland.

WHAT HAPPENED TO THE QUEEN; SOME DIARY NOTES

BY J. P. BRUMFIELD

All queens were clipped during the fruit bloom of 1913.

March 13, 1914: "All queens clipped in the latter part of January started up a little brood, but they have been pretty steady until now."

March 15, 1914: "I gave some partly filled combs of honey to some light ones and noticed some with a patch of sealed brood and some with recent eggs and larvæ. All the colonies in the yard have some brood."

April 15, 1914: "There is a colony that has no brood. I am not certain whether they have a queen. I did not find her when clipping (fruit bloom)."

April 16, 1914: "I found an unclipped queen in the colony, but she does not lay. I put a frame of eggs and larvæ in, think-

ing it would make her show her hand, but did not clip her."

April 22, 1914: "The queen is laying. There are drones flying in the yard."

April 29, 1914: "Her brood turned out to be drone. I united the colony by setting it on top of another hive."

My explanation is that about March 15 the colony lost their queen, probably by balling on account of an early disturbance. I have had this happen so often that I have resolved never to disturb a colony again before fruit bloom. The bees then raised a queen, and, on account of unfavorable conditions or lack of drones, she did not get fertile at so early a date.

Galena, Kan.

Heads of Grain from Different Fields

The Backlot Buzzer

You can teach a calf to drink from a bucket, but after a bee once gets educated to it, it sticks to the nursing bottle.

Yellow Wax from Bitterweed

The article by P. E. Waugh, p. 939, Dec. 1, on bees secreting yellow wax, and F. W. L. Sladen's comments upon it, brings to mind some observations in my own experience in Texas several years ago.

There is a plant, very common all over the north-eastern part of the state, known locally as dog-fennel, or bitterweed. Some seasons it secretes a considerable quantity of nectar which, however, is of such a very strong and bitter flavor that bees do not pay much attention to it if any other source is available. This plant thrives best on light sandy soils, and is in the prime of bloom during July and August, when the scorching sun and drouths of summer have ended the flow from most other plants.

Strong colonies will often store 40 to 50 lbs. of the rich golden-yellow honey; and comb built at this time is invariably yellow—just a little lighter colored than the ripe honey—and is clear and transparent. I know the color is not caused by pollen grains, for the pollen from dog-fennel is of a dull-red color. The new comb also has a slightly bitter taste, and I have often wondered if the very bitter honey consumed by the bees while secreting this wax could have imparted somewhat of the same flavor to it.

Down on the Texas coast we often get a considerable flow from goldenrod; and when heavy enough for comb-building I have noticed that it was always yellow. I am not sure that the color, in this case, was not caused by pollen, as it is of the same color.

How to Form Nuclei and Keep the Bees from Returning to the Old Stand.

The only way that I can make increase here and secure a honey crop is by forming two-frame nuclei. As you know, it is necessary to confine these nuclei for three days, else the flying bees will go back to the mother colony. Here is where my trouble comes in confining them. I have no shade for my bees, so I was afraid to close the hive entirely, so I accordingly left a hole half an inch square, over which I placed a piece of wire cloth. There were only two frames of brood and bees in a ten-frame hive-body. They struggled so hard to get out that they died by the handfuls. Then I tried giving them the full entrance, $\frac{3}{4}$ inch by the width of the hive, closing this with wire cloth, but it was no better. I sprinkled them with water, but it didn't do any good. There has to be some way to confine them or they could not be confined in cages and shipped as they are.

If you can give me any solution to the problem I shall greatly appreciate it. I have been thinking of putting them down cellar where it is cool and dark. Do you think it would be all right? and in that case how large an opening would you leave at the entrance?

I have been letting these nuclei raise their own queens; but this year I want to raise some queens and give them when I divide. I have never had any experience in queen-rearing; but I think I can do it all right. I want to use a modification of the divided brood-nest. Instead of using two perforated zinc division-boards, dividing the hive into three apartments, my plan is to use only one and divide the hive into two equal apartments and shut the queen in one side for ten days, and at the end of that time remove the cells from the queenless part and transfer the queen to that side, and let them raise cells in the other side, and so on as long as I need queens. What I want to know is, will the bees in the queenless side of the brood-chamber build cells of their own accord on the combs, or shall I have to graft and use artificial cell cups to get them to build? In confining the queen in this way to one side of the hive is it necessary to have perforated zinc over the entrance? If there isn't, will she not go to the entrance and get around the division-board and into the other side of the hive?

Would it be best to give a ripe cell to the above nuclei, or a virgin? and ought it to be given at the time the division is made, or wait till after the bees are liberated and quieted down?

In fumigating combs with sulphur, should it be put under the combs or on top? Will the fumes of the sulphur or carbon bisulphide injure comb honey? It is almost impossible for us to keep comb honey here in hot weather without worms getting into it.

Heiskell, Tenn., March 23.

J. R. STEDMAN.

[You will get the best results by making nuclei of sealed and hatching brood. The more brood that is just ready to come out, the better. Also shake into the nucleus box or hive nearly double as many bees as you expect to leave with it, getting as many young bees as possible. It is immaterial whether the nucleus has a queen-cell or a virgin queen, excepting that, where a queen is present, the bees will stay a little better than if queenless; also gains will be more rapid if there is a queen there to lay eggs. When the nucleus is prepared, simply put it on a new stand and close down the entrance, so that only two or three bees can pass through at a time; and as a precaution to get the bees to mark their entrance, throw a handful of weeds or straw loosely over it. Most of the old field bees will return to

the original stand; but if you are careful to shake into the nucleus, as advised, more bees than are needed, and have considerable hatching and sealed brood, you will have a nucleus that will build up rapidly. It is never a good plan to close the entrance of a hive, especially in warm weather.

Under normal conditions, with the honey-flow on and a strong colony, the plan of dividing the hive with a tight-fitting queen-excluder board is a good one for raising a few queens. The bees should start queen-cells of themselves. However, if there is no honey-flow on you will not get good results in any plan of queen-rearing unless you feed. It is not necessary to have perforated zinc for the entrance, as the queen never leaves the hive except in the case of swarming, and will not go outside of the hive to get around the division-board.

Carbon bisulphide is much better for fumigating combs than sulphur fumes. Sulphur will sometimes spoil comb honey, and is not nearly as effective as carbon. To use the latter, stack your supers of comb honey up in your work-shop. See to it that the bottom and the cracks between the supers are as nearly air-tight as possible. This can be done by pasting strips of paper around the cracks. Place an empty super on top of all, and in it an empty saucer or tin lid. Put in this receptacle about a teaspoonful of carbon bisulphide for every ten supers of honey. The gases are heavier than air, and will settle down through the supers. When fumigating with sulphur it must be placed *under* the supers instead of on top, as the gases will rise.—G. H. R.]

Fruit-jar a Successful Feeder

I believe I have a better method of feeding than I have yet heard of, although it is on the pepper-Lox order. Simply take a Mason jar—pint, quart, or half-gallon, according to the amount to be fed. Next take a lid, one that is of no use for sealing fruit any more. Break out the glass on the inside, and puncture the lid from the inside with a few very small holes and the job is done.

This feeder can be used the year round. I am using one now. The can will make the hole air-tight when I invert it, providing I have done a good job in boring. One can use this system regardless of the hive level. I use a small block of wood to cover the hole when it is not in use. The bees will glue it fast and make it air-tight.

In making this place for the feeder, take an extension bit, and set it so it will bore a hole just large enough for the can lid to come flush with the under side of the cover. I think the center of the cover is best. When this is done you have a feeder that is always at hand, and one that will never wear nor rust out.

Marion, Ind.

L. W. MARTIN.

A Cheap Milk-pan for Feeding

When using ten-pound pails for feeding, as J. L. Byer suggests, page 191, why not invert them in a pie-plate and set in a super on top of frames with the oilcloth turned back? This will avoid spoiling the pail-covers. All that is necessary is to insert a thin bit of wood or a shingle nail under the outer edge of the pail after it is placed on the hive, and then the bees will do the rest. It will feed just as fast as the feed is taken by the bees and no faster.

I prefer, however, a cheap milk-pan that holds about twelve pounds of syrup. I put a comb-honey or extracting super on the hive after sliding the oilcloth back about half way; set the pan over the open space, and put into it a handful of excelsior. I pour in the warm syrup just before dark, and, as a rule, the pan will be dry in the morning. I remove the cover and fill again if it is necessary. This can

be done in one-fourth the time required for pails. Grass can be used for floats.

ELIAS FOX.

Carrying Bees out of the Cellar Early in the Night.

My plan for 25 years has been to carry bees from the cellar in the fore part of the night. During the latter part of the night they will cluster compactly, and in the morning they will slowly unwind this "ball," and gradually begin their cleansing flight until all have been out. When the air is filled with bees, it is one of the grandest sights of the season. I never have that mad exciting rush that I used to have when setting out in any time of daylight. There is practically no drifting, even with hives only a foot apart and entrances wide open or partially closed. So far as setting hives on the former stand is concerned to avoid mixing, there is nothing to it.

Union Center, Wis.

ELIAS FOX.

Lead Pipe Dangerous

I notice, page 206, March 1, that E. B. Ault desires to use a lead spiral-worm pipe to convey steam through his honey-tank to prevent granulation or to restore the honey from its granulated state, and the editor asks if it is all right to use the lead pipe. I will state that it is not all right. The acids that are present in the best grades of honey are sufficient to set up a chemical action with the lead that will leave a lead poisoning; and when there are any acids present due to improper curing of the honey, as there are at times in a great amount in some honey, the chemical action is multiplied in proportion to the amount of acid present. I think a good grade of first-class white galvanized pipe a great deal better.

T. P. ROBINSON.

The Avocado Pear—More About It

The avocado, or "alligator" pear, is a great fruit, or perhaps should be classed as a vegetable, as they are eaten with a little vinegar, pepper, and salt.

At first taste very few people like them; but after tasting a few times one seems to want more and more, and doesn't seem to tire of them as with some fruits. I let them hang on the tree until they are ripe, then lay them away for two or three days, till they begin to get soft but "not too soft," picked too green they are watery and haven't the rich nutty flavor. The first avocado I ate I sprinkled a little sugar over, and a few drops of vinegar, and soon found them very nutritious. In Havana they retail from 2 to 60 cts. each, according to size and season. In New Orleans I saw large nice ones on the market 10 to 20 cts. each.

Corning, Cal., March 2.

HENRY HEAP.

Cement Hives in Florida

Mr. Culbreth, of Tampa, has had bees for years. He had a dozen cement hives made last spring, and transferred to them, hoping to have a good lasting and serviceable hive. Only one of these colonies is alive now. They say the cement hives are too damp for bees, especially in the rainy season. I should hate to handle many of them, even if bees should do well in them.

Palmetto, Fla., Nov. 5.

C. H. CLUTE.

Timbers under Water 20 Years

The editor's note, p. 952, Dec. 1, in relation to preservation of wood is correct. I have removed from lead and zinc mines timbers that I knew had been placed there and had been under water 20 years, and they were as sound and green as when put there. The bark and sap looked as though they had been recently cut.

OUR HOMES

Editor

Peace on earth, good will to men.—LUKE 2:14.

Charity suffereth long, and is kind . . . is not easily provoked, thinketh no evil.—I. COR. 13:4, 5.

"BREATHING-SPILLS."

When I am in Medina I am a Congregationalist; when here in Bradentown, Fla., I am a Presbyterian—that is, if the good brethren here will permit me to say so. There is no Congregational church here, and I do not see much difference, although dear Bro. Rood *did* suggest one Sunday that I would "know my catechism" better if I were an "out-and-out" Presbyterian. Well, I have learned to love the Presbyterians dearly. I love that little Sunday-school paper *Forward*, and I love the *Westminster Quarterly*. Just by accident my eye caught the clipping below from the *Adult Bible Monthly* for April:

BREATHING SPELLS

The United States Government has recently concluded peace treaties with more than a score of nations. Great Britain, France, Italy, Spain, and China are among the number; while Germany, Russia, Japan, Turkey, and Greece are expected to follow soon. The treaties provide that all international disputes shall be referred to a permanent commission for investigation.

The idea is that many difficulties will disappear upon careful examination, or will at least yield to adjustment. The most important arrangement of the new treaties, however, is the provision that in no case shall hostilities begin before the end of one year. If this provision is strictly observed, war will be practically impossible. A year's time to think will be enough in ordinary cases to bring about peaceful adjustments before war can begin.

These treaties have been aptly called "breathing-spell treaties," and they mark a great advance toward the permanent establishment of peace.

The principle is a very valuable one for human conduct. Men are apt to be too quick, both in speech and in action. Hasty speech brings ten thousand troubles into this world. Hasty action reaps a constant harvest of sorrow. The habit of taking time to think saves many a mistake and headache. Many an act that has caused trouble would never have been committed if the person committing it had but taken a breathing-spell.

When shall we learn that quiet and meditation have much to do with conduct? Prayer, also, is necessary to insure careful action. Think and pray before speaking or acting. A rule such as this would make the world a new place.

Anger is a hasty feeling of the heart. It bursts out into sudden speech or unwise action. The best cure for anger is to be quiet for a time. Wait until the fire burns out. There is an old proverb that runs like this: "If you are angry, stand still. If you are still angry, sit down. If after this you still feel angry, lie down."

The "breathing-spell" will work.

May the Lord be praised for what the above tells. How fervently we ought to thank God continually that we have a Christian President when such a one is needed—yes, *more* than ever before in the history of our republic. As I write, this 6th day of

April, the papers are full of the great temperance wave, not only in Ohio nor in the whole United States, but over the *whole wide world*. I fear I shall have to give up trying on these pages to give the notes of progress; for before it could reach you it would be stale news. I suppose you have all read over and over the declaration of Chancellor Lloyd George of England. He said in a speech, "We are fighting Germany, Austria, and drink; and the greatest of these three deadly foes is *drink*."

I have been much impressed during our recent Sunday-school lessons with the fact that in olden time, when God's people became disobedient and careless, he permitted ungodly nations to chastise them, even by wicked war and terrible loss of life. Well, it now begins to be made plain that this war was *permitted* because not only our nation but the nations of the world have been letting *rum* rule instead of Christianity and sober common sense. When the *whole liquor traffic* is ruled out and *down*, the war will cease. "He maketh the wrath of man to praise him."

Now let us come down a moment to "breathing-spells" for you and me, as well as breathing-spells for nations.

I have set seven hens during the past winter, and have 75 chicks, big and little. Every hen made a good hatch, and only two chicks died. I have spoken of my "tussels" with sitting hens; but I have been priding myself that I have learned by experience to "suffer long and be kind," but, alas! I think I must have forgotten what I have so often said to you along in the line of "breathing-spells." A young hen (part Leghorn and part Buttercup) had just brought off a nice brood. I was trying to teach them to eat bread and milk; but the mother got it into her head I was going to deprive her of the loved ones she had waited patiently to bring out. She flew at me in a frenzy. I coolly straightened up, but she made a dive at my foot and trousers leg, and for a moment I thought that, with beak and claws, she would tear the leg of my pants to shreds.* Let me digress. Mrs. Root had been scolding some time because I *would* wear such soiled and untidy pants when visitors, both ladies and gentlemen, faultlessly attired, were coming at all hours of the day to see A. I. Root and his garden and chickens. I had objected, claiming that every time I put on *new* pants something happened, and it did

* My scarred hands and wrists testified to the ability of a sitting hen along this line.

seem as if something was sure to "happen" the very first day the pants were worn. Well, dear friends, I had just donned the new pants, and this was the "happen." I gently sent her to the other side of the room, but she came back like a whirlwind, more fierce than ever. Now, I *thought* I was cool and gentle, but I am afraid I *did* say something like this: "Why, you old *heathen*, who do you think is running this ranch, any way?" I gave her a send with my foot that made her bump against the opposite wall harder than I had intended. She uttered a plaintive moan and then toppled over. In a moment she recovered and called faintly to her chicks, and then—what do you think? With one wing dragging she came at me again. About this time two things occurred to me. First, what a predicament I should be in if she *died* with a dozen motherless chicks! Second, it became apparent that she would *fight* with her last breath. It is seldom you can teach dumb animals who is "boss" by brutal kicks. They will fight as long as a bit of breath is left. May be you have tried it with a kicking cow or a balky horse, and, dear friends, *humanity* is much the same. Neighbors go to law and declare they will keep on, even if it takes the last copper they are worth. "Not by might, nor by power, but by my Spirit, saith the Lord of hosts."

Over in Europe we are now having an illustration of this great truth, on a terrible scale. How about the poor hen? She is alive and well, but she cares for her chickens with a broken wing dragging. A good deal of the time it gets between her legs, and must be very annoying. It is to me a constant lesson in regard to "breathingspells." My friend, how would *you* like to go through life, dragging a broken wing

between your feet and ankles? I must catch her and clip it off; but I dread another encounter, especially while she has the chickens.

Shall we not enforce our laws? Yes, our laws must be enforced for the good of community; but while we enforce them let us be *sure* to *pray* for the transgressor. Love ye your enemies, *do good* to them that hate you, etc.

The following, from *Farm and Fireside*, very aptly illustrates what we have been considering. Would not the same tactics close the great war now in progress?

A friend of mine bought a farm with a disputed boundary on one side. He and the owner of the other farm became acquainted, and each found the other a pretty good sort of fellow; but still that old boundary dispute stood between them. The time came for a new fence.

"Here's the line," said the old settler.

"I understand," said the new man, "that it is here."

"No," said the other, willing to cavil on the "ninth part of a hair," "we've always claimed this strip of land, and we must insist upon it."

"Now look here," said my friend, "I've had this line surveyed, and I haven't the faintest doubt that this strip is mine, but I think too much of your friendship to quarrel about it. Mind, I claim it's mine, but what *you* say goes. We'll build the fence on one condition—that *you* set the stakes. I'll make you judge and jury too. Set the stakes and we'll build the fence."

The old disputant squirmed. It wasn't fair, he said, to make *him* set the stakes. If he set 'em he'd set 'em on the correct line—he'd always claimed that strip, and he always would—

"All right," said my friend, "but you'll never get it by a lawsuit with me. You set those stakes and we'll build the fence in the morning."

The quarrel was settled. The stakes were set so as to take the strip from the man who set them—he had been neatly Glendowered.

I commend Glendower's policy to line-fence and boundary disputants everywhere. It may lose you a point once in a while, but it will save you trouble and preserve your self-respect.—*Herbert Quick*.

POULTRY DEPARTMENT

GREEN STUFF FOR CHICKENS, AND CHICKENS FOR GREEN STUFF.

The above heading is what I am going to talk about mostly; but incidentally I expect to wander from my subject somewhat. Since wheat is up "out of sight" I have been asking my poultry some questions, and they have (*I think*) given me some plain answers. I have, as you may recall, been giving the fowls corn and wheat in those elevated galvanized tubs whenever they felt disposed to fly up after it. At the same time we have sprouted oats for them to dig up, and usually some other kind of green stuff about every day. Added to all this

they have ground fresh bones about twice a week. Yes, there is one thing more. We keep a bin of middlings to mix up with various stuff from the kitchen; and with the small potatoes (too small to cook) boiled up and mashed with the shorts or bran. With the above "menu" we have been getting close to four dozen eggs a day from five dozen hens during March. We cut off the wheat, however, about the first of the year, and were feeling pleased to see the egg-yield keep up so well.

Well, a few days ago the hens were following me about, sometimes getting under my feet, and evidently wanting *something*

they hadn't been having. I thought it was more meat, and gave them more ground bones; but it was about the same. Then I gave a bigger allowance of the wet-up middlings, and that seemed to "hit the spot." When chickens have been lacking something, and finally get it, they will all go and sit down on a log, in a long row, and look satisfied and contented—at least mine do that way. To make sure it was the *wheat* they wanted, I gave them some chick feed that contained wheat, and they grabbed ravenously every bit of wheat. They had gotten *tired* of corn, and wanted their old ration. The egg-yield increased at once after they got it.

Well, I have been experimenting to find out, especially here in Florida, what we can grow to take the place of the expensive shipped-in grain. Cassava answers finely, as I have told you; but it takes a long time to grow it, and it can't be grown at all where there is much frost. I told you, whenever you set a hen, to sow some radish seed; and radish comes so quickly, and is so greedily taken by the fowls, I think just now it is one of the very *best* things, not only for growing chicks, but for laying hens as well. Mustard and turnips are too slow. I get from the Kilgore Seed Co., Plant City, Fla., an ounce of mixed radish seed for ten cents, and I wish you all could see the row of radishes from this one ounce sowed four or five weeks ago. Of course I put on a little guano; but the cost of the seed and guano, compared to the basketful after basketful of "greens" is but a trifle. Sprouted oats is a fine thing, and we owe a vote of thanks to Edgar Briggs for stirring up the poultry world about it, as he did, even if he did get pretty good pay for so doing. Lettuce and cabbage are both fine; but it takes ever so much longer to get a crop of either than it does of radish. Collards, a sort of cabbage grown here in the South, I am just testing, and this reminds me of a story I tell visitors.

THREE PAYING CROPS FROM THE SAME GROUND IN LESS THAN SIX MONTHS.

The strip of ground is next to the mulberry-trees, where I had my poultry-houses for perhaps three winters. In November we dug the dasheens then on the ground, and planted Triumph potatoes. These were dug and sold in February (\$2.00 a bushel), and collard plants set out. These last, from the start, were a "happy surprise." Some of the plants are now (April 2) 18 inches high and 30 across. I am told that down here, on good soil, you can pull off the lower leaves as needed, and the top will keep growing year after year.

I have recently seen a statement from some good authority, I think it was the *American Poultry Journal*, that if one were to give up either meat or green stuff for his poultry he had better stick to the "greens."

Some time ago I mentioned a little creek that crosses near one corner of our five acres. Well, this creek is mostly fed by the waste from artesian wells, and, of course, takes the drainage from excessive rains. One of our neighbors, Dr. Braymer, brought some watercress roots from New York and planted in this "run" some time ago. The roots or seed finally came down stream, and this winter there is a mass of watercress almost filling the stream from bank to bank, for almost one-fourth mile with some of the stems as large as a hoe-handle. A few days ago my neighbor Rood remarked he was almost ready to give somebody \$50 to clean out the stream so the water could get away during a freshet. I suggested *two things* to neighbor Rood: First, that the tremendous growth of cress was largely owing to the fertilizer that had been carried into the creek from his fields by the unusual rains of the winter. I think he has put on his 25 acres something like \$1500 worth. My other suggestion was that I would take it all away, without any \$50, for my 135 chickens, big and little. With all our books on poultry, why can't we have at least one on green stuff for chickens? Will not some one of our experiment stations get at it? or, better still, the Department of Agriculture, Washington, D. C.?

THE "BLIND HEN," ETC.

Now for the second part of our heading. What *breed* of chickens will take most kindly to green stuff in the place of grain? When the Brahmas first came out it was claimed they would live and lay almost without grain, if given access to a clover-field, and it is, I think, admitted that Rhode Island Reds live largely on green feed *if they can get it*. I have objected to them in place of Leghorns because it cost more to feed them; but, wait a minute. I have already mentioned a Rhode Island hen that laid big yellow eggs in November when we got here, and scarcely a Leghorn laid at all. Two years ago I bought of neighbor Rood two Reds because my Leghorns would not sit. Well, this hen is one of them. She is blind in one eye, and her egg is much darker than any other, so you see it is no trouble at all to "trap nest" her. When we got here in November she was laying two days, and then skipped a day. Soon she laid three days, and then a skip, and a little later she laid every day. As I felt sure from former experience she would soon

want to sit. I paid little attention to it; but when the blind hen laid a yellow egg day after day through December, January, February, and clear into March, without ever a "cluck," I began to "sit up and take notice." This is *her third winter*, mind you. I have set seven hens, and have 75 strong and healthy chickens, and every setting had more or less yellow eggs from the blind hen. Some good authority has said there may be a lot of great layers scattered over the land, but the owner *doesn't know it*. She happened to lay a different egg, and be blind in one eye. I give here a clipping from *Farm and Fireside*:

LEARN TO DIAGNOSE HUNGER.

Lowering the cost of keeping chickens is not given half the attention it should receive. The majority of chicken-owners think their birds need grain when they act hungry and restless. The first move is to throw a lot more of expensive grain to allay the restlessness of the hens. In most cases what the birds are asking for is green, succulent, bulky food, fresh water, grit, and animal food or bone.

The heavier breeds in particular would be much better off in vigor and productiveness in many cases if half of the costly grain were replaced with a good quality of cut or ground clover or alfalfa hay, some roots, cabbage, apples, potatoes, or silage. By such a change of feeding costs can be reduced.—B. F. W. THORPE.

Over and over again, where you read of remarkable success with chickens you find it was made by being right with the fowls, and making a careful study of the whole matter. The clipping above hits it exactly.

DWARF ESSEX RAPE.

Some time ago, while "down East," I visited a poultrykeeper who had his fowls in a yard full of rape two feet high or more. He wanted to show us a \$50 hen; but she kept hiding in the luxuriant rape, so it was almost impossible to get a sight of her. Now, this is the ideal condition. Have your rape-patch large enough, or your flock of chickens small enough, so they won't eat the rape all off clean in a day or two. I have a small enclosure full of rape now that pleases me; but if I were to let the whole 135 in it at once I fear there would not be a green leaf by night. What can we grow that will take care of itself like weeds, almost or quite without cultivation or fertilization, and that the chickens will eat? There is waste land, more or less, almost everywhere (as well as down here in Florida) doing no good to anybody or anything. Mulberries fill the bill pretty well; but they are not "greens."

P. S. Whoever writes that book on "Greens for Chickens" should keep in mind we don't *want* a book at a big price with very little real "greens."

FETERITA: MORE ABOUT IT AS A SUBSTITUTE FOR WHEAT.

As I haven't seen any thing in High-pressure Gardening about feterita I thought you would like to test it in Florida. I am sending you a sample under separate cover. Plant 12 to 18 inches apart in the row. I think it is a great chicken feed, and it makes heads in Kansas without rain.

Concordia, Kan.

LEWIS EELLS.

P. S.—We think feterita good boiled, and eaten with cream.

The "P. S." is the "big thing" about the above letter. Having some of the grain on hand, we boiled it in a farina-boiler, and Mrs. Root and I as well as the neighbors were "happily surprised" to find it a really delicious, nourishing food, even better than the dishes made from the flour. Now, here is the great point: Grow it in your garden; put the heads of ripe grain in a bag (I have just done it), thrash, and cook. Can any "shorter cut" be made "from producer to consumer"?

ON THE BOOKSHELF

The Country Home Month by Month.—Edward Irving Farrington. Laird & Lee, Inc., Chicago, \$2.00.

One of those wholesome, readily understood manuals of country living is this new work by Mr. Farrington, sometime editor of *Suburban Life*, and a writer on general rural subjects. Beekeeping justly claims its share of his attention in a series of reminders, month by month, of what to do in the apiary—in May, prevention of swarming; in October, preparation for winter. "No country home is complete without a colony or two" is a broad statement, but one of which the backlotter and farm beekeeper will realize the truth.

For the general farmer who wants suggestions for beginning beekeeping along with his monthly hints on farming, gardening, and stock raising, this work is designed. "With painful recollections of the many occasions on which the author has remembered things to be done just too late to do them, this book has been written with an intent to help others in doing the right thing at the right time." Not a treatise on beekeeping, it would not instruct a specialist in beekeeping in anything he does not know already. The notes on apiculture are orthodox, however, Mr. Farrington being a member of the craft himself.

ENGINE POWER COSTS LESS NOW

Read My New Free Book

Before you buy any kind of an engine. Note my lower prices:
2 H-P \$34.95; 3 H-P \$52.50; 4 H-P \$69.75;
6 H-P \$97.75; 8 H-P \$139.65; 12 H-P
\$197.00; 16 H-P \$308.80; 22 H-P \$389.65.
*Portable engines proportionally
low. 5-Year Guarantee.*

WITTE Engines

Gasoline, Kerosene, Distillate, Gas.

Besides lower prices, WITTE engines use less fuel per horse-power hour, by one-fourth to one-third—enough saving to pay entire cost of engine in a year. Easy starting; no cranking; steady running. My 23 years of one thing, making WITTE engines, makes my higher quality.

Buy Direct, Cash or Easy Terms

Why pay more for reliable power, than for what the WITTE will furnish it? You pay engine price only once, but fuel costs money every day you run. My engines cut down the fuel cost.

My Free Book Tells how it is done and shows in figures how the saving is made. Also tells you where to look for quality in any engine. Write and get my book.

Various Methods of Wintering in Idaho

WE hope to show next fall the methods used by J. J. Anderson, of Salem, Idaho, in wintering his bees in eastern Idaho. He is one of the best beekeepers in the valley, and there are many of them there. In this connection it is fair to say that this territory is already well stocked with bees.

Our Cover Picture

WHEN the total number of apiaries in cities is considered, the proportion of complaints because of the bees is seen to be very small. If the beekeeper is careful where he locates the bees, and if he handles them intelligently, there is really no reason for their becoming a nuisance at any time. A good deal depends upon where the hives are placed. If there is an alley or passage-way directly in the line of flight the bees at certain times of the year are sure to make trouble.

The picture on our cover for this issue shows a well-placed city apiary belonging to Chas. Y. Hake, of York, Pa.

How Bees Have Wintered

LATE reports show that bees have wintered unusually well, taking the country as a whole; but there were quite severe losses in Pennsylvania, New York, northern Ohio, southern Michigan, and a 10 to 25 per cent loss in and about Denver, Colo. There seems to have been some unfavorable weather or fall flora, or something in the regions mentioned, that caused a loss of anywhere from 10 to 50 per cent of the bees. The losses seem to have been heaviest in parts of Pennsylvania and New York, ranging anywhere from 25 to 50 per cent. Most of the reports from Michigan are unusually good, and the prospects for clover in both Michigan and Wisconsin are excellent.

In some of the southern states the bees have not built up quite as well as usual.

Wintering Outdoors in Single-walled Hives

A FEW days ago we looked over a couple of apiaries some fifteen miles east of Medina. The bees were in single-walled hives, exposed to the north and west; and yet, remarkable to relate, they wintered in good condition. Fortunately there was no aster nor other fall sources of honey in the vicinity. The hives were filled with the best grades of honey. One owner said he had not touched the brood-nests for over a year. He just let them alone. He had taken no honey from them, because he said he thought they would need all they had. He was wise.

The other man had taken quite a little crop of honey, but left enough in the hives, for he likewise had not disturbed their brood-nests. The colonies were strong when they went into winter quarters; and the fact that they had not been tampered with was probably one strong reason why they wintered so well.

A few colonies in double-walled hives, however, showed up stronger than those in the single-walled. This only goes to prove that with good stores, young queens, and strong colonies, bees will winter sometimes in spite of wind exposure and only a single thickness of wood between them and the weather. That they will do better in double-walled hives was also proven.

Is a Pair of Frame-tongs a Necessary Tool for a Foul-brood Inspector? Some of the Troubles of a Bee Inspector

ONE of our state inspectors, Mr. A. C. Ames, of Peninsula, Ohio, is using frame-tongs for pulling frames out of hives. While this tool is not particularly needed in modern apiaries, it is almost a necessity among the old-fashioned or farmer beekeepers who do not disturb their brood-nests from one year's end to the other. Frames are often badly spaced, too far apart or too close together, or, even when properly spaced, so tightly glued down that it is

difficult to remove them, even when a good tool or pry is used to break the propolis connections. Poor spacing results in comb attachments so that it is impossible for the ordinary pair of hands to get a good grip on a frame of comb. It is then that a pair of frame-tongs with double jaws comes in very handy.

We have heretofore not thought much of such a tool, but we are beginning to believe that supply manufacturers ought to furnish something of this kind for the use of inspectors.

On some jobs they should have a hatchet, chisel, crowbar, frame-tongs, bee-gloves, bee-veil, clothes more than sting thick, and the patience of Job. We have gone with foul-brood inspectors on various occasions, and we know of the exasperations that one meets in trying to go through some hives of bees. Home-made hives and home-made frames, neither of which fit the other, make a combination which, if they have not been tampered with for three or four years, will exasperate even an angel. An old box hive or a log gum could not be worse.

The New Queen-cage Candy; How to Make it

So far the tests are proving satisfactory with the queen-cage candy made of invert sugar and ordinary commercial powdered sugar. The brand of the former that we have been using is called nulomoline, made by the Nulomoline Co., 111 Wall St., New York. This product is used in exactly the same way as honey. As there may be some who are not familiar with how to make Good or Scholz candy we will give our method.

The invert sugar, or nulomoline (or honey of best quality) is heated to a temperature of about 140 degrees Fahrenheit. This is not to sterilize it, but to make it mix better with the powdered sugar. The latter is poured into the hot syrup little by little, and stirred until the mixture cannot be stirred any more. It is then placed on a board which is covered over with powdered sugar, and handled like bread dough and flour. More sugar is kneaded in until a stiff dough is formed.

The success or failure in making this candy all depends on whether *just the right amount of sugar* is added to the honey or invert sugar syrup. If too much is put in, the dough will be too stiff and hard, and the bees will starve on it; if not enough, it will "run," daub, and kill the bees. We make our candy so that it will hold its shape and position when the temperature of the candy

and of the atmosphere around it is 90. This is about as hot as summer weather ordinarily becomes; and unless the candy will stand that temperature it will flatten out and "run" in very warm weather.

Of course invert sugar or nulomoline cannot transmit foul brood; and if it can take the place of honey, other things being equal, it is greatly to be preferred. So far the new candy remains moist longer, and has a better flavor than that made with honey boiled for 20 minutes to sterilize it. This long boiling we believe is what killed so many bees and queens in the mails of last year.

Honey-crop Conditions; Clover Prospects and Prices

DURING the last few days, according to the Weather Bureau maps to which reference was made on page 349 of our last issue, there have been general rains over the greater part of the United States. All reports show that the prospects are good from what white clover there is in sight. In some localities it is reported that there is only about one-half the amount of clover that there has been in former years; and even if all other conditions are favorable there will be only half a crop. In other localities there seems to be the usual amount of clover. The drouth of last fall, and the winter-killing of last winter in some places, have been responsible for the reduction in the clover regions.

There have been general rains in Texas, and the prospects are good for a crop from that section of the country. The early rains in California gave mountain sage a good start, and the prospects were excellent. A partial drouth followed, but this was quickly dispelled by frequent rains that began on April 23d. These have continued with more or less frequency ever since. These rains, according to those same Government maps, have been general over all California. There will be a light crop of orange-honey, and a fair crop of mountain sage. Had it not been for an intervening drouth and the hot winds in southern California the crop of mountain sage would probably have been record-breaking.

Professor Baldwin reports a good yield from orange at Deland, Fla. Whether others in his state are as fortunate as he we have not yet learned.

In Colorado and some of the other mountain states it has been reported that the mountains contain less snow than usual. This may curtail somewhat the yield from alfalfa. There will be the usual good yield of alfalfa in the Imperial Valley.

To recapitulate: There will be from one-half to two-thirds of a crop of clover; slightly under an average of best grades of alfalfa; from one-half to a fair yield of orange in California; from one-half to two-thirds of a crop from mountain sage; full crop in Texas.

Practically all the comb honey of the better grades is cleaned up. There should be a strong demand for new No. 1 fancy comb honey.

The price of extracted will probably rule about the same as last year. But in order to get this, more comb honey should be produced this year than last or extracted will slump in price. The heavy sale of sections warrants the belief that there will be more produced.

Later.—Just as we go to press our manager at Los Angeles writes as follows:

Southern California in general has had a series of light rains coming one on top of another. This should greatly increase the chances for a good sage flow, while it has undoubtedly injured the possible output of orange honey inasmuch as the oranges have been in full bloom during the period of these rains, and consequently the flow has been shortened by just so many days of rains, clouds, and cold. This will much more than be made up by the benefit to the sage.

Bees Necessary in Southern Grape Culture

FACTS of pollination are of the utmost importance in fruit-growing. Every horticulturist knows that some classes of fruit will yield lightly, if at all, when far from other varieties, and that, for best results, not only should varieties be selected that pollinate well together, but some provision should be made for the transference of the pollen. The wind cannot be relied upon for this work.

The Muscadine grapes, according to the North Carolina Experiment Station, are self-sterile—that is, the vines which produce fruit must be fertilized by pollen from other vines. The only vines capable of doing this bear no fruit. So it is necessary to plant both the male and female vines close together, and thus insure that the pollen be carried from one vine to the other.

Unfortunately bees are not nearly so active on the blossoms of the Muscadine grape as they are on other plants. The small proportion of flowers which develop into fruit can probably be traced to this fact. Says Bulletin 209, "Every effort should be made to encourage bees. It is very evident from our results that at least one hive of bees should be kept where any large number of vines are grown."

The Muscadine grape is more important in the South than any other. In North Carolina it is estimated that more Muscadine grapes are grown than all others combined. They flourish from Delaware south to Florida, and west as far as Texas. Points of superiority over other grapes lie in their resistance to insect pests and fungous diseases, their ability to grow in poor dry sandy soil, and their immunity from frosts, due to their tardy blooming period.

Oregonian Beekeeping

"Beekeeping for the Oregon Farmer," by H. F. Wilson, Entomologist Oregon Experiment Station, Bulletin No. 168, Oregon Agricultural College.

The bulletin opens, following the introduction, with a short history of bee culture in Oregon. The author believes that bees were first imported the year after the discovery of gold in California, and that they were brought along during the great rush for the Coast. A considerable amount of gold must have been discovered in the bee business, for the first colonies sold for \$125 a colony. Following this early importation not many more bees were brought in, the rest developing largely from those imported by the early settlers.

The early portion of the report is a survey of the present situation of apiculture in Oregon—practically the same matter which Mr. Wilson prepared for GLEANINGS, page 895, December 15, 1913. Most of the honey comes from central Oregon, while the Columbia Basin is second, and southern Oregon third. On the average, one out of four farmers keeps bees. A distribution map has been prepared showing the approximate number of 50,000 colonies. These are worth, roughly, \$250,000.

"For the actual amount of money invested there are few agricultural pursuits that will give returns as great as those that can be made by beekeeping," encouragingly asserts the writer; but he is careful to add that, "like every other agricultural industry profits in beekeeping are secured by hard work and careful attention to business."

The rest of the bulletin is given over to a discussion of the bee business in its manifold phases. His remarks under the head "Why and When Beekeeping does Not Pay" are valuable in accounting for many of the failures. Varieties of bees, necessities of equipment, types of hives, manipulation, and general management to avoid or overcome the obstacles which sooner or later confront every beekeeper, are all dis-

cussed in such a manner that the pamphlet is made a short text-book, valuable not only to the Oregon novice but to any one else taking a hand in the game.

=====

Bees and Fruit-bloom in and about Medina

OUR readers will remember that fifty-acre apple-orchard some ten miles north of Medina, and how that the proprietors of that orchard have desired to have a large number of bees in it. It will also be recalled that the first year the present management took charge of this orchard they secured, with the help of the bees, and by spraying and trimming, 16,000 bushels of apples. The following season was not as favorable, but they took another big crop, but not as large as that of the previous year. This year we again put some fifty colonies in the orchard; and yesterday, May 6, we drove down there to see how the bees were working on the blossoms. The trees had not all come into bloom; but some where the blossoms matured had plenty of bees on them. In fact, there was a distinct roar such as one hears near basswood-trees. A glance upward showed hundreds and hundreds of bees; and it also showed something else. Some little flies, or bees, or what looked like bees, hovered in the air. These latter would occasionally alight on the center of a blossom; but they were by no means as persistent and active as the honeybees. They would hang and poise on the wing like a humming-bird, then dart like a bullet in one direction or the other. Sometimes they would alight on the green leaves, and at other times on the petals of the flowers. Sometimes we caught them in the act of helping themselves to pollen; but they made no effort, so far as we could discover, to get at the nectar at the base of the blossom.

We were so much interested that we made another trip, taking our head queen-breeder, Mr. Mell Pritchard, who is also the "bug man" of the A. I. Root Co. Some of the bees which he saw he pronounced the solitary sand bees, a very small black bee with a head like that of a common honeybee, but very different in its general appearance. Some call them sweat bees. There was still another kind of bee or fly that was more numerous than the last named. They were smaller than honeybees, and looked very much like small yellowjackets. They had yellow bands, and the ones which we captured showed that they had pollen on their legs and on their bodies. While they were very numerous in the orchard, and no doubt were doing something in the way of pollin-

ating blossoms, they were by no means as industrious and persistent as the honeybees. The latter would seem to rush from blossom to blossom in the greatest haste. One bee would pollinate a hundred blossoms while these flies would pollinate only one.

On coming home Mr. Pritchard pulled out his authority (Comstock's book), and identified these bees as the *Diptera*; that is to say, they were not bees but *flies*. The description showed plainly that they were the yellow-banded species belonging to the genus *Syrphus*. They do much good by destroying colonies of aphids. There are other species of this family that resemble bumblebees, and others the honeybee; still others the wasp. One species "so closely resembles a common honeybee," says Prof. Comstock, "as to be often mistaken for it."

In this connection we have wondered whether in that Pejario Valley, California (see GLEANINGS, p. 305), where there are 15,000 acres of apple-trees, and where it was alleged no bees were needed, there were not present myriads of these flies. In referring this matter to the Entomologist, Professor H. A. Gossard, of the Wooster Experiment Station, Ohio, he gave it as his opinion that there was nothing to prevent these same flies from being present provided there were colonies of aphids for them to feed on. You will remember that the Horticultural Commissioner of Pejario Valley, supported by Professor Woodworth, of the University of California, stated that the apple-trees of that valley did not require the presence of the honey-bees; that the two varieties of apples grown there, the Newtown and the Bellflower, were self-fertile. One of these, the Bellflower, is known to be sterile to its own pollen in the eastern states. We have just been wondering whether or not either of these varieties does not require the agency of bees or insects. We proved that there are bees in the valley; but it is evident that there were not enough to pollinate such a vast number of trees. Is it not possible that the syrphus flies are doing this work? On the other hand, Professor Gossard explains that there is quite a difference in the formation of the blossom of the same variety of apples in the East and in the West. If this is true it may account for the fact that a variety that is self-fertile in one locality is sterile to its own pollen in another. In the one case the pollen cannot reach the ovaries of the blossom without the help of insects, and in the other no such help is needed. This whole question is an interesting one. If any of our readers can solve the problem we shall be glad to hear from them.

Spraying Trees Just Before the White Petals Fall; Is the Practice Dangerous?

WHILE Mr. Pritchard and ourselves were making observations at the big orchard north of Medina we discovered that the bees would ignore certain of the apple-blossoms, and that those that they did visit showed that the anthers of the stamens had turned slightly brown. This would indicate that the blossoms before yielding nectar must be ripe. Mr. Pritchard also called our attention to the fact that the bees actually visited and stayed longer on the old blossoms where the white petals had entirely fallen off. We thought he must have made a mistake; but after a little scrutiny we found numerous cases where the bees were gathering nectar from the old blossoms without a single white petal on them.

To-day Professor Gossard came down with Mr. Walworth, the bacteriologist, to get some material for another investigation. We drove them over to this orchard. He found, just as we did, that the bees were gathering nectar from these old blossoms from which the petals had fallen. Mr. Walworth then dissected one of these and found considerable nectar, although the blossom was denuded of all bright colors.

This has a practical bearing to those who have bees in the vicinity of orchards. It means that we have been spraying our trees at the wrong time. The usual instructions sent out recommend applying the spray just about as the white petals begin to fall. The supposition has been that at this stage no more nectar is yielded, and hence no bees would be killed; but the observations made by Mr. Pritchard, Prof. Gossard, and Mr. Walworth and ourself, show very clearly that bees gather not a little nectar *after* the petals have fallen. If arsenate of lead is poisonous to bees, which is ordinarily applied at this time in the form of sprays, then the recommendation to apply the poison just before or after the petals fall is *just at a time* when considerable damage will be done. It would seem, then, that our instructions should be modified so that the arsenate-of-lead sprays shall not be applied until several days after the petals are gone.

The year that our neighbors in the fifty-acre apple-orchard secured such an enormous crop of apples was the year when they sprayed just before the petals began to fall; hence they must have sprayed when the blossoms were yielding a large amount of nectar. Whether this spraying killed our bees we could not tell. If so, there were no dead bees or brood showing about the hives.

In view of the facts above stated, and that

some do not believe that arsenate-of-lead sprays kill bees, we shall have to say we don't know; and yet we have on file large numbers of reports that look very much as if the bees had been poisoned by the thousands by spraying when in full bloom.

=====

G. W. York, Former Editor of the American Bee Journal, Statesman and Lawmaker

ON our recent western trip we had the pleasure of meeting our old friend George W. York, who for many long years was sole owner and proprietor of the *American Bee Journal* as well as its editor, and who, prior to that time, had served in the capacity of assistant editor and manager under Thomas G. Newman for several years. After many years of arduous labor, Mr. York sold out to the well-known business men and beemen, Charles Dadant & Sons, of Hamilton, Ill. Mr. York never claimed to be a practical beekeeper, and never posed as such in his regular editorial columns. He said to us recently that the *American Bee Journal* had improved in one respect; and that was, there are practical beemen at the head of it as publishers and editors, and he noted with great pleasure the apparent life and growth of the journal. After the continuous strain of many years of hard labor, during which Mr. York did the work of two or three men almost every day of his life, he began to feel the need of a change. A business opportunity presented itself, and he sold to his old friends the Dadants, as before explained. He then went to Sand Point, Idaho, going into the fruit and dairy business, where there was entire change of profession, climate, and surroundings away from the turmoil and noise of a big city. One can scarcely blame him for doing this, for sometimes there come periods in one's life when a change in profession, although it sometimes results disastrously in a financial way, is desirable. Mr. York, however, in the parlance of the day, is making good. While as he says he is not getting rich quick, he is making a living, and is happy and well. His picture taken expressly for this journal shows it. He is happy, because he is outdoors right next to Nature. Bees? Yes, he keeps a few.

It was not long before the people of Sand Point, Idaho, began to discover in Mr. York not only a friend and neighbor but a citizen. Much against his protest he was elected a member of the city council; and when he got into that body there was something doing, for Mr. York initiated a movement to clean out the undesirable element of his

town. It was not long before they began to think of him as a fit candidate for Representative from his county. He has been a life-long Prohibitionist; but as there was no organization of the Prohibition party there, the Republicans insisted on his running as a Representative. He protested that he was not a Republican, that he had never had any inclination to get into politics, and he much preferred to stay out of it. But tremendous pressure was brought to bear, with the result that he consented to have his name used, with the understanding that his friends would not expect him to do a single thing toward his own election.

"You leave that to us," they said. It is unnecessary to say that he was overwhelmingly elected.

When he went down to the legislature he was anything but a nonentity. In fact, he soon became one of the leaders in the House. As might well be expected, while he bore the Republican label he was still a Prohibitionist at heart. A temperance wave was sweeping through Idaho, and many members of the General Assembly were elected on that issue. Mr. York was not afraid to show his colors, and the result was he was regarded by every one as one of the real leaders among the Republicans and Democrats of the House. So far as we can ascertain, he was the real leader in temperance matters, but this he denies.

Both the House and Senate were overwhelmingly temperance; but a few of the minority in the upper house attempted to filibuster. The House passed one temperance bill unanimously. Mr. York and his colleagues finally told the bunch that the House would not pass a single bill of any kind until they passed the temperance bill. The wet Senators concluded that it was a mere bluff. Things went on in this way for a couple of weeks without the House passing a single Senate bill. Finally when they saw that the members of the House meant what they said, they passed the bill, and shortly after passed other temperance bills that will make Idaho in 1916 the dryest of all dry states in the Union. A great deal of credit, no doubt, belonged to our old friend York for this.

Some of his colleagues told us that he was tactful, courteous, and had a way about him that would melt all opposition. When it was necessary to fight to the last ditch, Mr. York would be found in the fore front. He disclaims any credit for what he did for the temperance and other measures.

We have before said in these columns he was the father of one of the most drastic foul-brood bills that was ever put before a

legislature. It passed the House and Senate by a large majority; but the reform governor, not properly understanding it, vetoed it. For particulars see page 258. It was certainly no fault of Mr. York that the bill did not become a law. He and his friends interviewed the Governor, and explained the thing in all its details; but apparently His Excellency did not understand, and vetoed it on the ground that it provided for too many inspectors, not noticing that the law was properly safeguarded on this point, by a limit on the general appropriation—\$5000—a modest sum in this day and age. Other states have used as high as

GEORGE W. YORK

\$10,000, and some have gone as high as \$30,000.

We saw Mr. York busily at work in the House before he knew we were in town. He seemed to be one of those legislators who are always on the job.

This legislature of which our friend was a member presented a remarkable contrast to what the former one had been; and the fact that there was one man, or several of them, who believed in churches and Sunday-schools, in this General Assembly, provoked no little comment. Mr. York was in general demand to speak before churches and Sunday-schools, and it seemed almost a novelty for a Representative to stand up in the pulpit and talk about God.

Dr. C. C. Miller

STRAY STRAWS

Marengo, Ill.

REPLYING to J. A. Heberle, p. 379, I think heather is not to be found in this country. A patch was once started, in New Jersey, I think, but did not succeed. As he says, heather honey is not considered first-class in Germany, but, somewhat curiously, in Scotland it is counted the finest in the world.

ALL the while I'm learning more and more that rules good for me may not be good for others. One of the things that I think I know for certain is that it is not advisable for me to supersede any queen merely on account of her age. Now comes P. C. Chadwick, p. 353, and says he lost 10 per cent of his two-year-old queens in winter and spring, and not one of his one-year-olds. If I had his locality, or his bees—I wonder which it is—I'd suffer no two-year-olds except a few extra good ones.

GLAD to see that good word about Editor Bixby, p. 304; but why didn't you tell us about his wife? I suspect she's the better man of the two. [If she is not the "better man" she is certainly his equal. She knows how to make muffins to go with honey that are superior to any thing we have ever tasted anywhere. If they could be sold at either of the great expositions on the Pacific Coast, with honey and butter on them, they would draw crowds—yes, a regular stampede of people. She is just as much interested in bee problems as any beeman we ever met. It is not often that we find a woman so enthusiastic about her husband's business. She did and could keep up with two bee editors, and that is going some.—Ed.]

IONA FOWLS, I'd give a pretty penny for a talk with you. You say, p. 377, that Mr. Alexander "took bees that had not begun swarming." Yes, but he also took bees that had started cells, for he especially directs to look the hive over to see if it contains cells, and "If it does, destroy them." (See A B C and X Y Z, p. 365.) In GLEANINGS for Aug. 15, 1911, p. 490, to which you refer, I replied, to a question, that brood over an empty super would not start swarming below; but I didn't say, and I didn't think, that swarming would be started if there was nothing but an excluder between the queen and the brood above. In fact, that's the very thing I've done many a time, after cells were started, and even after

swarming, and I don't remember that I ever did it before cells were started. And I count it a sure cure for swarming.

J. L. PEABODY, the 83-year-old who appears on page 343, is the man who invented the first honey-extractor I ever used or saw. He's the man of whom beekeepers may feel proud. [One of the privileges we had at the National convention held at Denver was to see and hear Mr. Peabody. The president invited him to the platform to address the meeting. Notwithstanding his early connection with the honey-extractor, he was very modest in saying that not he but his brother should be given the credit for building that early machine. He was generous to say, however, that A. I. Root built a better machine because it was geared up. He then went on to tell his early experiences, all of which was interesting, because we were listening to a man who was one of the early pioneers, and whose name has been linked with those of Langstroth, Quinby, Wagner, Gallup, Tupper, and others of those early days; and while we are about it we might as well link our own Dr. Miller with the group.—Ed.]

YOU'RE trying, Mr. Editor, p. 347, to find why aster stores act differently in different localities; and while you're at that you may as well tell at the same time why your bees work on aster and mine don't. Asters and goldenrods a-plenty here, but seldom a bee on them. [Can't answer that question; but next fall we hope asters will not yield in our locality. If the aster honey should all be used up in brood-rearing it would do no harm; but asters yield such an infinitesimally small quantity that the poor bee that is out in the field after it must go miles and miles and miles through swamp brush tearing its wings before it can get a load. In our opinion bees will wear themselves out in working on aster—more so than on any other honey-plant. One apiary that we had near the Akron swamp was in fine condition by the first of September. By the first of October those same colonies dwindled down to half their former strength. It looked as if half of them had been poisoned. The real fact is, that the aster bees had worn themselves out by long flights, and died a natural death. This left the colonies about half strength, with bad stores for winter. Fearing that these stores might kill them we moved most of the aster bees to Virginia, where they could have a flight every few days.—Ed.]

J. E. Crane

SIFTINGS

Middlebury, Vt.

"Setting bees out of the cellar," by E. S. Miles, p. 222, March 15, is full of good advice, and well worth the careful attention of inexperienced beekeepers.

Mr. Doolittle, page 224, March 15, discusses record-boards in his usual common-sense way, and I, for one, agree with him that there is nothing better than a smooth board.

Mr. L. H. T. Stone, of Cambridge, Mass., wants to know what I meant by single hives well packed, Jan. 15. Well, I meant just one colony in a case instead of four as Mr. Holtermann packs them.

Dr. Miller says, page 177, March 1, "I may say that my bees in the cellar are never entirely quiet. There is always at least a gentle murmur, something like a soft breeze through pine-trees." Thank you—just what I wanted to know; just as good as going into your cellar myself. Mine is the same.

I received this week a sample of scarified sweet-clover seed from C. P. Dadant. A lot of it that I placed between damp paper, less than two days ago, has already nearly all sprouted. I believe this treatment of the seed is going to prove a great help in introducing this clover and getting farmers to sow it. Of 72 tests made by the Department of Agriculture an average of only 36 per cent germinated.

Hawkweed, or paintbrush, as it is often called, is one of the farmer's worst pests here in Vermont, and it is getting to be quite common. It spreads by underground roots as well as by seeds. The seeds are winged like the dandelions, and the wind carries them everywhere. It seems to thrive on all sorts of soils. I have worried for fear it would ruin our bee pasture when it becomes more abundant, as it surely will. It seems to be utterly worthless, and quickly runs out our native grasses in pasture and meadow. A farmer, however, in a nearby town has discovered that sweet clover will clean it out and produce a forage crop of value. One more mark to the credit of sweet clover.

Mr. Byer, p. 178, calls attention to a statement of Arthur C. Miller in the December number of GLEANINGS that "any lively

youngster is supposed to be able to do the trick" of making candy, and enquires how I feel now. Pretty well, thank you. How do you feel? Now, the trouble with me was not in the making, for I made most beautiful blocks of candy as hard as bricks. But the trouble was they wouldn't stay made. I set most of them away in a cool room until I wanted to use them, when they began to soften on the outside and run, and the block would bend, and twist out of shape. What a mess! I suppose I used too large a proportion of honey or corn syrup. Thanks to Mr. George H. Rea, page 150, Feb. 15, one pound of honey to twenty-five of sugar is about right.

After speaking of "Upward Absorbents vs. Sealed Covers," the editors of GLEANINGS say, page 90, "Strictly speaking we did not use sealed covers, but an arrangement that was a compromise between the two extremes." "This is the arrangement that at Medina has generally given us the best results." Exactly; and I believe this will give best results in most places. All that is needed in upward ventilation is to get rid of the moisture and no more. Old cloths coated with propolis, a board or two pieces of boards laid on loosely, or even a glass with a slight crack around the edges, answers every purpose. It doesn't take a great deal to let it escape. We do not think alike, often, because we do not understand each other.

Langstroth wrote more than sixty years ago, "I come now to mention a substitute for liquid honey, the value of which has been extensively and thoroughly tested in Germany, which I have used to great advantage. It was not discovered by Dzierzon, although he speaks of its excellence in the most decided terms. The article to which I refer is plain sugar candy, or, as it is often called, barley candy. It has been ascertained that about four pounds of this will sustain a colony during the winter when they have scarcely any honey in the hive. If it is placed where they can get access to it without being chilled they will cluster upon it and gradually eat it up. It not only goes further than double the quantity of liquid honey, but is found to agree with the bees perfectly; while the liquid honey is almost sure to sour in the unsealed cells, and expose them to dangerous and often fatal attacks of dysentery." Is there anything new under the sun?

BEEKEEPING IN CALIFORNIA

P. C. Chadwick, Redlands, Cal.

Old Dutch Cleanser is excellent for removing propolis from the hands.

Dr. Miller, page 261, April 1, advises planning ahead to have extra combs of honey to feed bees instead of making candy. No better advice could be given regarding this matter.

Look at the picture of a ten-dollar honey-house, page 327, April 15, and see if you think it could be built for that price in California. It looks to me as though it would take two carpenters a day to build it, which would figure eight dollars for labor alone.

Uncle Sam has kindly sent me one of the new cook books for using honey. It has some dainty recipes that I am anxious to have tried.

Later.—I see my wife looking at those recipes, which makes me believe something good is coming.

Redwood hives should always be nailed with cement-coated nails. When redwood gets wet the water and wood have a tendency to form an acid that eats metal very rapidly. The cement coat prevents this to a great extent. I use a seven-penny cement-coated box nail for nailing my hive bodies, covers, and bottoms.

Louis H. Scholl, in the March 15th issue, says: "But after all, the secret is to begin to prevent swarming before the desire to swarm has ever awakened in the colonies." Splendid advice—splendid! In one apiary of 170 colonies I have not had a single swarm issue this season. No cells have been clipped to prevent it, and other apiaries in the vicinity have been wild with swarming.

The editor's remarks on Dr. A. J. Cook are well deserved, and entirely fitting the man. I have smiled on several occasions, especially at our state conventions, when some small caliber opened up a rapid fire on this big 42-centimeter character. Dr. Cook has left an indelible impression on the beekeeping world as well as in other lines, and no amount of criticism of this versatile character can undo what he has done. We need more men like him—big, broad, scientific men.

I am indebted to Mr. E. Ockerby, of Western Australia, for a government pamphlet entitled "Bee Farming." It contains some very interesting information regarding the bee industry in that great and only partially developed country. I have more to say of this later. Mr. Ockerby is but a boy in years, but a man in knowledge. He is one of a company of some thirty-five boys who are selected from the Young Australian League, which is much the same as the Y. M. C. A., to tour the United States to gain knowledge and experience through travel. No boy can be selected for this trip who does not come up to a certain mental, physical, and moral standard. The expense of the trip is paid partially by the Australian Government, partially by the parents of the boys, and partially by money derived from entertainments given by the talent of the company. No one in this company is allowed the use of tobacco—in fact, they have no desire for it. They are now traveling toward the East. Should any of my readers meet with them, treat them kindly. They are bright boys, but most of them are poor.

Rainfall has been quite general over the southern part of southern California, ranging in amount from one-fourth of an inch to one and one-half inches. The extreme southern end received the most. As far north as Ventura and Santa Barbara counties no report of rain is given, and the presumption is that none of consequence has fallen that far north. The value of it remains to be seen; but it is my opinion it will be of no great help this season to any thing except possibly the white sage and late buckwheat. The button sage has not developed as it gave promise of doing at one time. There is little hope in many localities from this source, and nothing very big may be expected from it in any place. Hope for a crop from it has already been abandoned in some localities. The orange bloom was never better, and never yielded more nectar; but the best part of the blooming period has passed with the sun under the clouds, and the bees unable to work. The crop from this source has been more than half lost by bad weather. In fact, the general outlook at this writing for orange and sage honey is anything but promising.

BEEKEEPING IN THE SOUTHWEST

Louis H. Scholl, New Braunfels, Texas.

TWO PROGRESSIVE COUNTY ORGANIZATIONS.

I have just had the pleasure of attending a meeting of the Bexar County Beekeepers' Association, at San Antonio, Texas. I am pleased to note the number of organizations of beekeepers increasing in Texas. Time and again I have called attention to the importance of such organizations.

The officers are, Lewis Maverick, president; J. K. Smith, vice-president; E. G. LeSturgeon, secretary-treasurer; Henry D. Grossenbacher, foul-brood inspector. The standing committees appointed are: Wm. Cravens, chairman Legislative Committee; S. A. Gould, chairman Committee on Bee Diseases; A. P. Heinen, chairman Entertainment Committee; Wm. Zimmerman, chairman Program Committee.

The other organization is the Frio County Beekeepers' Association, with Pearsall, Texas, for its postoffice address. George Curtis is president; J. N. Mayes, vice-president; B. I. Gilman, secretary-treasurer; B. F. Cude, sergeant; R. A. Little, foul-brood inspector. On committees are E. G. LeSturgeon, O. E. Milam, and Guy Wood, Program Committee; Frank Talbot, C. T. Hardy, and F. T. Lester, Bee Disease Eradication; J. C. Campbell, C. G. Mayes, and J. C. Eldridge, Entertainment Committee.

THE TELEPHONE IN BEEKEEPING.

It is a great gratification to the beekeepers that the rural telephone is finding its way into all portions of the country. Nearly all of our apiaries are now located within easy reach of these rural telephones, and they are a blessing in the many ways these can be put to use. It is now quite an easy matter to get information from any of the localities that we are not able to visit ourselves. Most of the owners of the land upon which the apiaries are located have telephones. As they have more or less interest in the welfare of our work with the bees on their place we need only call them up for the information desired.

In several instances such persons have called me up of their own accord to remind us of swarming going on, or that it was their belief that more storage room would be necessary on account of a sudden honey-flow. Only yesterday morning I had a call for help because a heavy downpour, a veritable cloudburst of rain, was threatening one of our apiaries. Had I not received this

hurry call, and dispatched men to this apiary eleven miles away immediately, I should have lost all the bees there. In the afternoon another call advised us of several colonies of bees swarming at another apiary. I went there immediately and hived them. With these telephone connections it is far easier to keep in touch with the bees and conditions at the various apiaries, though they be very much scattered, and at long distances from headquarters.

PROSPECTS IN TEXAS.

Beekeepers generally all over Texas are jubilant over the prospects for a honey harvest. Abundant rains during the last few weeks, and the opening of spring, have finally resulted in all kinds of vegetation making rapid rank growth and in great profusion. The bees are in excellent condition except in a few localities where they have run exceedingly short of stores. Some were "robbed" too closely last fall, and are handicapped by heavy brood-rearing that began very early this year on account of the mildness of the weather in the latter part of January and throughout most of February. Although much cold weather followed thereafter, particularly through March, when we had snow and ice, and some of the coldest weather of the winter, the bees did not suffer. The colonies were exceptionally strong; and with the large amount of brood, which has a tendency to keep the hives warm also, they came through the cold weather, and some of the colonies cast large swarms as soon as warmer weather came.

INVENTORS OF NEW HIVES.

It is all right for P. C. Chadwick to encourage would-be inventors of new hives, page 53, Jan. 15, provided they really invent something worth while. Otherwise I feel it actually a duty to discourage it. I have on my desk just now a long letter, accompanied by drawings and a patent, from another inventor of a new hive that, in the mind of the originator, will revolutionize beekeeping. To any beekeeper with the slightest experience and some idea about only the general requirements of a good hive, this new invention is but a complicated, impracticable clap-trap affair—even more so than the same kind of inventions of six persons I have received such correspondence from.

Far better it would be if we could dissuade these over-enthusiastic people from

spending a lot of hard-earned money on patents that cost much but which are worth but very little if anything at all. I have more faith in a gradual evolution in beehive improvement than in any radical changes; and I believe also that it is an admitted fact that beehive patents are not very popular with beekeepers of experience; and in spite of the scores of beehive patents that have followed the introduction of the Langstroth hive there has been very little hive improvement through the efforts made by their inventors.

ALMOST ABSOLUTE SWARM PREVENTION.

I have been exceedingly successful in swarm prevention upon every occasion when I was able to do the "stunt" at the proper time. This "knocking swarming in the head" has been described by me before; but I cannot help mentioning it again, as it continues to prove successful, in my hands at least.

To the experienced beekeeper it is well known, or should be, that swarm prevention ought to be begun by the beekeeper before the bees have the "swarming fever." I found, long ago, that after the desire to swarm has been allowed to come over a colony of bees, and conditions for swarming are favorable, it is exceedingly difficult to keep them from carrying out this desire. Consequently I begin operations for this purpose prior to the time swarming actually begins although I have had many satisfactory results from swarm-prevention manipulations, even at times when the bees had stolen a march.

Most of the readers will remember that nearly all of my bees are in divisible-brood-chamber hives. It will also be remembered that I have explained how we winter the colonies in three of these shallow stories, preparing an upper super with shallow extracting-combs partly filled with honey for additional winter stores. I have also mentioned the essentials of this additional super for breeding room in the spring, insuring more powerful colonies, and keeping the bees contented longer than with the old way of crowding them into a smaller brood-chamber. Besides furnishing the extra breeding room this super takes care of any honey not needed in the brood-chamber in the spring, and consequently prevents the clogged brood-nest and a crowded condition, so conducive to swarming.

The above-mentioned conditions already keep the colonies contented longer; but a congested condition of the brood-nest can prevail in even the most roomy hive. And I discovered, many years ago, that the

mere addition of room above, below, or even all around such a congested brood-nest may not prevent swarming if conditions for swarming are at all favorable. It is absolutely necessary to break up this mass of brood in order to arrive at the desired results. It is for this reason that combs of brood are replaced in the brood-nest with empty ones or with frames filled with foundation and by various other methods. I aim at the same thing, but in a quicker manner and with less labor.

The manipulations consist of simply exchanging the two lower stories of the hive, placing the lower one on top of the second, which now rests on the bottom-board. Usually most of the brood of the colony is in the second or middle shallow story. The lower one is partly empty, especially in the lower part of the combs. Thus the most of the brood is switched to the bottom, and the empty comb of the former lowest story is now immediately above this, or right in the center of the brood-chamber where it ought to be. As there is nearly always some honey in the upper portion of the combs of the super, now on the bottom-board, and which is now in the center of the brood-nest, the bees soon move it and it is carried out throughout the honey season.

The super is replaced on top of the hive of all normal-sized colonies. It contains some brood and mostly honey unless the colonies have run short of stores, as they sometimes do when breeding heavily. If a colony is very strong, or in the event it is not long until the honey-flow may begin, another super, with the frames filled with full sheets of thin super foundation, is given underneath the shallow extracting-super, and the usual method of tiering up supers thus provides additional room.

If this manipulation is made shortly before the swarming season, and plenty of room provided after that, there is hardly any need of another exchange of the halves of the brood-chamber. This should be watched, however, and a second manipulation made if necessary. The work is carried out so quickly, especially if two work together, and the results obtained are so valuable, that it pays to do it. It hardly takes longer to make a complete operation of the entire hive, as described, than it takes to open up and remove one comb from the regular deep-frame hive when it is desired to exchange combs of brood for empty ones or for frames with foundation. According to my idea the brood-nests are left in a better condition after manipulations than in the deep hives cut up by the inserted combs or frames of foundation.

GENERAL CORRESPONDENCE

HOW TO TELL THE AGE OF LARVÆ BY THEIR SIZE

BY G. M. DOOLITTLE

[Several times our attention has been called to the fact that very little has been given which would enable a beginner to tell much concerning the age of a queen larva by observing its size, in, say, a fraction of an inch from day to day; also the age when it straightens out in a cell, the age when it is capped over, etc. We feel that, of all our writers, Mr. Doolittle is perhaps the best qualified to take up a subject of this kind. If there are others who disagree with him we should like to hear from them.—Ed.]

The mother queen lays the eggs for the queens, drones, and the multitude of workers which appear in any colony in the swarming season. From three to thirty eggs for queens (according to the race of bees and the prospects of the season) cover the colony's preparation for swarming. From a few hundred to as many thousand for drones (mainly in accord with the drone comb the home of the colony affords), and for from sixty to one hundred thousand workers, which are all provided by the one mother of the colony. So far as the unaided eye can detect, these eggs are just alike as to size, color, etc., an egg laid in a queen-cell, which is not far from $\frac{3}{8}$ inch in diameter, being exactly the same as the one laid in a worker-cell which is only about 3-16 in diameter. The eggs for drones are just like the others, except that they are not fecundated. All of these eggs remain about three days in the egg form. Their length is not far from 1-16 inch, and their diameter about that of a fine cambric needle, or something like the period mark used in common printing. In fact, on a cloudy day it needs pretty good eyes to see these eggs, as they are attached to the bottom of the worker-cells; but with the comb in which they are laid held so that the sun can shine down to the bottom of the cells, they are quite plainly discerned, and very much admired by all who visit my apiary and see them attached and standing on end.

At the proper time, or about ten or fifteen minutes before the eggs should hatch, the nurse bees apply a little chyme, or what one writer calls "the milk of bees," to the eggs, when they soon go out of sight and a larva appears. Just what becomes of the "egg-shell" was a question I was always wishing more light on, but so far I am in darkness. A larva just hatched is even harder to discern than the egg, as it lies in a partially curved state floating on its milky food at the bottom of the cell. All I can think of as describing it would be a coarse spider-web, or a very fine hair, a little more than 1-16 inch long, and quite a little smaller at each end than at the middle. When twelve hours old this larva has assumed a crescent

form, something like the new moon, and about the size the egg was from which it hatched. By shaving the cells down so they are only $\frac{1}{8}$ inch deep, and holding them with the open ends so the sun will shine on the milky food, these larvæ can now be seen quite plainly, even to the motion of the mouth as they are feeding, for they are voracious eaters at all stages of their larval existence. I have many times used these twelve-hour-old larvæ for queen-rearing; but after many experiments I do not consider them any better than those 36 hours old. At this age the bees accept them, which they are not inclined to do nearly as readily as the older ones.

When 36 hours old the larvæ are still further "coiled up," something like a cat when preparing for sleep, and have attained a length of about $\frac{3}{32}$ inch, their diameter in the largest place being about $\frac{1}{32}$ inch. These are the larvæ which I always select, as nearly as may be, for transferring to the cell cups when rearing queens. From many experiments and much careful observation, such larvæ as these are the ones selected by any colony of bees during a copious flow of nectar, where the apiarist takes away the queen that the bees may rear others to take her place, or for his use in the apiary. At 48 hours the larva has reached a length of about $\frac{1}{8}$ inch, and a diameter of about that of a coarse sewing-needle. If such larvæ are still floating on the milky food, good queens will result from their use, but otherwise they should be rejected. At 72 hours the larva has nearly doubled the size it was 24 hours before, and attained a length so that the extremities nearly or quite touch each other as it lies curled up in the bottom of the cell. A careful observation at this stage will reveal that, with the majority of colonies in a normal condition, very little chyme can be seen in the bottom of the cell, or surrounding the larva, which shows that they are being fed a coarser food so that they may become the working force of the colony rather than fully developing them for becoming a mother.

From now on to the sealing of their cell,

little if any food will be discovered in their "feed trough." But I note that our questioner asks about a queen larva. Up to about 60 hours old all larvæ are treated alike as to their food—that is, they have before them all they can possibly eat, all the while, and "enough is as good as a feast." The larva in a queen-cell floats on a "sea" of chyme. The larva in a worker-cell floats on a "lake" of this same milky food. But when they pass these hours, the "sea," with the larva intended for a queen, becomes an "ocean," while the "lake" of the larva intended for a worker becomes first a "pond," and then that dries up altogether, a coarser substitute taking its place. In other words, all fecundated eggs give queen larvæ to all intents and purposes up to the time such larvæ are 48 hours old, and the food given by the nurse bees thereafter decides their fate. A 96-hour-old larva can be changed over to a partly developed queen, which will become fertile and lay fertile eggs for from a few weeks to a few months; but these are small in size, and soon "play out" entirely. As a matter of existence, such a queen will carry along a colony so that, through her supersedure, the colony may go on to a fair prosperity again.

As regards the further development of the queen larva: It grows very rapidly from now on, and at the end of about $5\frac{1}{2}$ days after hatching it is about one fourth larger and longer than is a worker larva when six days old. At this age both are sealed over, after which both commence to spin their cocoons preparatory to the pupa or nymph stage and the emerging of a perfected queen or worker; but there is this difference—the queen larva is fully developed in about seven days, while it takes twelve after sealing to perfect the worker, this time being somewhat lengthened or shortened by the temperature of the weather and the activity of the colony.

And now, Mr. Beginner, pardon just a word: If you wish to reach the full stature of an apiarist along all lines of our beloved pursuit, just take the time to go over the whole ground in this matter yourself. Get the A B C and X Y Z of Bee Culture spread out before you regarding this matter of "from the egg to the perfect bee," and prove by your own observation and experiments whether the writers of the past have found out all there is to be known on this subject.

Borodino, N. Y.

SWARM PREVENTION

BY J. E. HAND

G. M. Doolittle ingeniously likens the swarming impulse of bees to a broody hen. While agreeing that the similitude is perfect, I am not in sympathy with his method of eliminating the broody condition. A wide experience with poultry has taught me that a pullet of a good laying strain will seldom become broody during her first season, and an equally wide experience with bees has taught me that queens are less inclined to broodiness and voluntary supersedure (which is the direct cause of swarming) during their first season. While this trait in bee nature is not sufficiently developed to warrant depending upon ordinary methods of supersedure for swarm prevention, I have ascertained that a correct method of queen supersedure is the more safe and economical solution of the swarming problem. The question is, how shall we prevent swarming with the least expense for labor and equipment, the most important factors in the economics of honey production?

While the broody condition that usually culminates in swarming is shared by bees

and queens alike, we have found that the remedy is more effective and much more economically applied to the queen with as little disturbance of the brood and bees as possible. These are excessive manipulations that multiply the cost of honey production. We learned a long time ago that destroying queen-cells to prevent swarming is equivalent to shoeing a broody hen off the nest to prevent sitting, and that both are a waste of time and energy, for the broody hen will return to her nest, and the broody queen and bees to their queen-cells. Dropping the analogy relative to the hen, the question is, "What is the more economical and practical method of eliminating this natural condition of broodiness that usually results in swarming?"

Shall we resort to the excessive manipulation of hives and combs, removing brood that will soon become bees, and peddling them promiscuously about the apiary, all of which excessive manipulations are involved in the shake-swarm method advocated by Mr. Doolittle? or shall we practice the equally laborious method of removing

queen-cells once a week, involving excessive labor in manipulating brood-chambers heavy with supers as advocated by R. F. Holtermann and others? or shall we practice dequeening with its deleterious effects upon the working qualities of bees, likewise involving excessive manipulation of brood-chambers heavy with supers, to detect signs of swarming? I repeat it, Shall we resort to the abnormal condition of queenlessness with its psychological depression upon the energies of bees, as advocated by Dr. Miller?

Is such excessive labor conducive to economical honey production, the desideratum of every method of beekeeping? Since swarming is a natural impulse, it is imperative to combat it with purely natural principles. Assuming that all preconstructed queen-cells are supersedure cells, the supposition is that their construction indicates a desire for a young queen. This supposition becomes an established fact when the

correct method of requeening eliminates queen-cell construction with its attendant evil "swarming." Here is the method, requiring as much time to do it as to name it. "Remove the queen and insert a ripe queen-cell, removing cells while looking for the queen."

The story is told in sixteen words, and the operation is performed in as many minutes. If done with a strong colony at the beginning of clover harvest, swarming is prohibited by a combination of purely natural forces; and the desire for a young queen being satisfied, the colony will work with a vim and energy that denotes contentment and satisfaction—a psychological condition that cannot be maintained by combating nature by abnormal methods. I might deliver a long discourse explaining the philosophy of the principle, which might be only theorizing, hence I will only say, "Try it and be convinced."

Birmingham, Ohio.

INTRODUCING A QUEEN BY DEMORALIZATION

BY A. C. AMES

A great deal has been written concerning the introduction of queens; but yet little has been said in support of one of the best methods in use, and that is the introduction of a queen to one to three pounds of bees which have been placed in an unnatural condition. It is a well-known fact that when bees are in a demoralized condition one can do many things with them that cannot be done otherwise. This way of introduction may be varied to suit local conditions. The main point is to have the bees in an unnatural condition.

The plan I favor is as follows. Shake from one to three pounds of bees into an empty hive. The bottom of the hive should be fastened and the entrance stopped. To keep the bees from freely leaving this hive I usually wet the inside with water and leave about a quarter-inch of water in the bottom. Then, to make sure they are thoroughly demoralized, I put the cover on, bump the hive on the ground, and give them a good rough handling.

With the last bump I land all the bees in the bottom, lift the cover, and place several combs in the hive, the number of combs depending on the amount of bees used. I now either run the queen in the entrance or just throw her in among the bees in the bottom of the hive. These bees are now

either carried to an outyard and released, or, if to be kept in the yard that the bees came from, they are confined for two or three days.

It may look as if this is a whole lot of work. It is more work than some other methods, but the results are sure—at least that is my experience. As a way of making increase after the main flow, it is excellent. At that time there is always a lot of bees which can well be spared for this purpose.

When I wish to replace a poor queen I usually try this method. After the queen has started to lay I take brood from the queen I am going to discard, and with the help of the two queens it is possible to build the new colony to good strength very quickly.

Keep the poor queen at work until all her hive makes a good place to go to get a frame of brood when one is wanted, or her stock can be used for further increase. At the end of the season the remnant of her colony can be used to strengthen some weak colony for winter. In this way one gets the full benefit of a queen which is going to be discarded. Where one has several of these queens in a yard their brood is a big help in making increase or keeping the yard in first-class condition for strength.

Sixty colonies in the mountains near Hanford, California.

SITTING TIGHT FOR BETTER PRICES

BY M. J. SAIN

We have fine prospects for a good crop here this year, and splendid prospects of having to keep on storing away our honey for future use. Just as long as we have free trade, I suppose we producers of honey, as well as the olive-oil producers and a few others, will have to use lots of grit, and hold on until a change comes. I shall be one who will hang on. I can keep storing it away as long as I can sell enough here and there to buy the lumber to make room for it.

My bees are in fine condition this spring

—the best I have ever had them. I expect to run for comb honey in the sage flow this year, which will be my first attempt at this to any extent.

My apiary in the mountains consists of sixty colonies in ten-frame Langstroth hives. They produced eight tons of honey, but no increase to amount to anything since the honey-flow came on unevenly. One day we would enjoy a good flow, and the next almost nothing. I believe this was due to the windy weather.

Hanford, Cal.

HONEY EXHIBIT AT THE MINNESOTA STATE FAIR

BY P. J. DOLL

Minnesota people are naturally proud of their State Fair, which is always held the first week in September. The grounds, covering 265 acres, are located midway between Minneapolis and St. Paul. The combined population of these two cities is over 600,000. Nearly 400,000 visitors attend the State Fair every year.

These people are a patriotic and unselfish lot. They enjoy prosperity in a state of boundless possibilities, and wish others to enjoy the same blessings, so once a year they get together and show to each other and to the outside world what they have been

doing the past year and invite others to come and share with them the bounties Nature has lavished on their state.

It would take a large volume to tell of the different exhibits at the fair, so in this short article I shall confine myself to the honey exhibits alone. The Minnesota Beekeepers' Association, working with the fair management for a number of years, has built up the honey exhibit from year to year until now we probably have the largest and finest display of honey ever made.

The Apiary Building, used exclusively for the display of honey, wax, bees, and

M. J. Sain's apiary in a young apricot orchard.

bee-appliances, is 144 feet long by 70 feet wide. More than \$700 is appropriated for the maintenance of this building. Besides, there is appropriated \$1168 for premiums on honey, wax, and bees, making a total of nearly \$1900 annually devoted to the encouragement of beekeeping.

The premium honey is all displayed in fourteen glass cases arranged around one side and both ends of the building, about five feet from the wall, so visitors can go all around each and every case to inspect the display, and also so all the honey is visible at one glance inside of the building. In the center, against the other side wall, is conducted a demonstration of extracting honey.

In 1913 this extracting demonstration was one of the big sensations of the fair, when Francis Jager, now professor of bee culture at the University of Minnesota, brought 12,000 pounds of honey to the Minnesota State Fair in nice, clean, white extracting-frames, just as the bees made it, in well-painted, well-constructed supers. This honey was uncapped, extracted, bottled, and labeled during the fair week, for the entertainment and instruction of the public.

A speaker on the platform explained how the bees gather honey, pollen, and propolis; how bees make wax; the difference between comb and extracted honey, and explained in detail the workings of the extractor, which was kept running all the time. Two men were uncapping honey with steam and

electric heated knives over a Peterson capping-melter. Another man managed the four-frame power-driven extractor and pump which emptied the honey into two one-hundred-gallon storage tanks.

Above the bottling-table was a honey-heater which could be regulated to heat the honey to any desired temperature before putting it into bottles. Two girls were busy draining the honey into quart, pint, and small bottles. Two more girls at a counter near by were giving free samples of honey on triskets to the public. In this way 57,000 helpings of honey were passed out during the week, and about 15 gallons of honey were used up.

People crowded around the place all the time. The daily papers of St. Paul and Minneapolis had write-ups about this demonstration every day for ten days. It certainly pays to advertise, especially when the advertising doesn't cost anything, and we did not pay the newspapers one cent in money; but we did occasionally slip a bottle of honey to some of our good friends who helped our cause. I am convinced that a small bottle of honey well placed will do more good than a ten-dollar note.

This demonstration alone cost the fair management about \$500. They insist that we must have it again, and this year we are planning on extracting 30,000 pounds of honey, using all the different kinds of extractors, wax-melters, and implements used by up-to-date beekeepers. We also will try to work up some kind of contest to show

which kind of extractor or capping-melter is best adapted to the needs of different classes of beekeepers.

On the same side of the building with the demonstration of extracting honey were the displays of three different bee-supply dealers who are allowed space for display of their goods at a very small charge. On the same side, also, was a glass observation hive with both sides of all eight frames exposed to view, covered with live bees which had free access to outdoors through a hole in the wall. Right near this were specimens of Minnesota honey-bearing plants, pressed and dried, and put into individual frames, with its name below each plant.

In front of the main entrance to the Apiary Building there is a little park in the shape of a triangle with a nice well-kept lawn trimmed with flowers. In the center of this spot there was an octagon-shaped screen cage, about eight feet in diameter, in which there was a sort of vaudeville performance with live bees. This proved very interesting to the public, and attracted people on all sides, who, after being entertained with the live bees outdoors, would be induced to go inside and see the other attractions inside of the building. Our main trouble was that our building was too small to accommodate the crowd who wanted to get in.

Around different parts of the fairgrounds we had twenty-two colonies of live bees flying at will right among the people. Strange as it may seem to many beekeepers, nobody seemed to be afraid of the bees. Little children were playing in front of the hive

entrances, letting the bees crawl over their hands, and thinking it great fun. I did not hear of anybody getting stung, and I was around every day and all the time.

I don't believe there is a better way to advertise honey. No doubt it was worth thousands of dollars, and it didn't cost the beekeepers one cent. Beekeepers ought to take more interest in their State Fair exhibits. That is where people come to look and learn. They are not in a hurry; and if you will present something interesting there is no trouble in getting an audience all the time. If beekeepers will all help to advertise honey this way, there will be such a demand for honey that the price will be considerably advanced.

It is estimated by conservative people that Minnesota now produces about 2,000,000 pounds of honey annually. Most of this is consumed by the farmer beekeepers and their neighbors. Less than half finds its way to the cities. Less than 500,000 pounds of this comes to Minneapolis and St. Paul—not enough to give everybody in these two cities a pound each during the year.

Beekeepers talk about overstocking the market with honey. No doubt the public is willing to buy all the honey we can produce, even if it were fifty times as much, which would be only enough to give everybody a pound a week. It is true that in this city there is sold three and four times as much western honey as there is Minnesota honey; but I believe the market in all parts of the United States could be developed to consume all the honey we are able to produce.

Minneapolis, Minn.

BEES AND BERRIES; BEES TROUBLESOME AT STRAWBERRY-PICKING TIME

BY JEAN WHITE

There seems to be quite a difference of opinion as to whether bees damage fruit or not. I keep bees and raise small fruit, and I am quite sure that I should not care to raise some kinds of fruit in the vicinity of a large apiary. A small beeyard and a small-fruit plot would show practically the same results. The bees do not harm the fruit until it becomes fully ripe and sweet. At this stage they are able to suck the juice from the berry, and do so. My strawberries, red, black, and purple raspberries, all showed this plainly. Every fruit that was over-ripe was sucked as dry as if evaporated for market. In picking, it required the utmost care to avoid picking a bee, as some berries would have two, three, and sometimes four

bees upon it. As I raised fruit before raising bees I noted the dry berries quickly, never having seen any until the bees worked upon them.

I am of the decided opinion, notwithstanding the so-called proof that bees do not puncture fruit, that in the case of thin-skinned fruits of considerable sweetness when ripe, they do break the skin to get the fruit sugar. Bees that can and will eat a way through a paper or cloth placed between them and liberty, or between them and honey or some substance that they particularly desire to get at, can, if they so desire, easily puncture the skin of the ordinary raspberry. Birds may and do break a good many; but as the raspberry or black-

berry is a collection of tiny separate parts, not all of them would be broken; yet the raspberry in a short time is sucked perfectly dry of juice. My bees did not work extensively on the strawberries or blackberries, although they did some work there; but the red raspberries they were as crazy for as they would be for a lump of sugar. Raspberries cannot be picked very unripe, as they adhere to the core, and crumble if forcibly removed. If picked closely every day I do not think the bees would injure many; but in picking for home use, or for markets near by, I feel sure the bees would take their toll quite freely. They did of my home berries picked every other day, but left till fully ripe, as otherwise they are sour and not of as good flavor as when sweet and ripe. I firmly believe they puncture the thin delicate skin themselves, or it may be that it is so thin that they suck the juice through it.

Bees were not nearly so plentiful among the fruit-bloom in the spring as in the later season among the fruit. For home use this was not particularly annoying; but I can well believe that in commercial fields they might do a good deal of damage. As I preferred bees to berries I was not distressed; but I can see that the fruit-man might not feel just that way about it. As larger fruits are usually picked for market before fully ripe they very likely would not prove very troublesome; but with small fruit sold near at home, and not picked until ripe, I am quite sure bees would prove a nuisance.

Bees are supposed to fertilize cucumbers. Our cucumber-beds were within a few rods of the bees this season. They did not produce as well as they should. I hardly ever saw a bee near them. Whether this was because of better feeding-ground near at hand, or because the large leaves from the vines hid the blossoms completely, I do not know; but the bees did not visit the cucumbers as freely as I should have expected them to.

Glover, Vt.

[It is a well-known fact that bees will work on overripe fruit, and they are often troublesome in this way, especially at fruit-picking time. It has been definitely proven, however, that bees cannot puncture the skin of the fruit. It must be punctured by some other insect, by a bird, or, as sometimes happens, by bursting due to the overripe condition. Now, then, the question is whether such fruit as is punctured by birds or insects, or burst because of being overripe, is of any value, commercially speaking. Such fruit will always rot almost immediately, and the contention of the bee-keeper has always been that the bees in sucking the juice from such really unmarketable fruit is no loss, for the fruit then dries up and the rot is not communicated to other fruit close by. This is especially true in case of grapes, and should also be true, we think, in the case of strawberries.]

Bees are used so extensively for pollinating cucumber-blossoms that we feel sure there were other flowers more attractive to the bees in blossom at the same time.—ED.]

VALUE OF BEES IN STRAWBERRY CULTURE

BY L. T. FLOYD

Some time ago while traveling I chanced to mention to some people whom I met that we had received one thousand dollars for the crop of strawberries we had grown on an acre on our farm at Central Norton. From them the story found its way into the local paper, and since then we have received many inquiries about it; and as the subject seemed to be of interest to so many I want to state one of the reasons for our getting this crop in a year when berries were generally a failure.

We had a fairly good stand of plants on this patch the season before. They wintered fairly well, but the spring was backward and cold. They began to bloom about June 1. On the night of June 4 we had a heavy frost which killed all the blossoms down to the smallest buds. We thought our crop

was doomed, because we remembered a season about seven years before when a lighter frost ruined our crop. This was before we began keeping bees.

The evening after the frost it rained—a good soaking rain. This caused the plants to set more fruit-buds. Out of the crowns where one or two fruit-stems had been before, there sprang many more; and in about ten days the patch was white with blossoms again. Near this patch we had fourteen colonies of bees, and at this time of year the hives were brimming full, and every fine day while the plants were in bloom one could hear their busy hum quite a distance from the patch.

The spring being so cold, there were very few wild bees or other insects, and so we had to depend solely on our own bees for

the fertilization of these blossoms. They made a good job of it.

How do we know? Because, as the season drew near its close, every blossom that had not been frosted grew a berry. There were none of the small hard knots often seen toward the close of the harvest.

How much do you think those bees were worth to us on that crop of berries? We place it at hundreds of dollars, but this is only an estimate.

One thing we are sure of, and that is that it pays well to have a good crop of berries in a year when they are scarce, and high in

price. We know the bees were largely responsible for this.

We had more than half these berries picked before it began to dawn on us that we were going to have a crop. We had been sure the frost had fixed them. The sooner that fruit-growers find out the benefit that our little friends are to them, the sooner they will catch the dollars that are slipping through their fingers because of imperfect pollination. The profits in bee-keeping are not all to be counted in the number of pounds of honey harvested.

Central Norton, N. B., Canada.

BUSY BEES OF BELGIUM

BY JAMES B. PAIGE

In describing the country traversed by the railroad between Liege, Belgium, and Aix-la-Chapelle, Germany, Baedeker in his "Guide-book of Belgium and Holland" says: "The country traversed by the line between Liege and the Prussian frontier is

remarkable for its picturesque scenery, busy manufactories, and pretty country houses, while the engineering skill displayed in the construction of the line is another object of interest. The picturesque stream which the line crosses so frequently is the Vesdre, and

pleasant glimpses of its wooded banks are obtained on both sides of the train. This is the most beautiful part of the journey between England and Germany, and should if possible be performed by daylight."

Having had the pleasure during the past summer of making the journey in the reverse order given by Baedeker, that is, from Aix-la-Chapelle to Liege, by automobile, over an excellent macadam road that followed the railroad and river the greater part of the distance of 38.9 miles, as registered by the speedometer, the writer is in position to state that the author of the guide-book has in no particular exaggerated in his description of the beauties of the country.

At Tulpie, 5.7 miles

Jos. Crutzen's apiary, Quatre Chemins, Henri Chapelle, Belgium.

from Aix-la-Chapelle, one traveling by automobile goes through the ordeal of a custom-house inspection. This concluded and the journey resumed, he arrives at the first town in Belgium, Henri-Chapelle, where the well-tilled farms, large herds of cattle, capacious barns, and neat and comfortable houses, surrounded by flower and vegetable gardens, testify to the industry and thrift of the Belgian farmer and his family.

In a limestone section one naturally expects to find an abundance of white clover and other nectar-producing plants. In this respect the valley of the Vesdre is no exception to the rule, for white clover grows everywhere in profusion.

Under such conditions an apiary constitutes a valuable asset to the equipment of a farmer, more especially a Belgian farmer, whose areas for cultivation are relatively small, and who must, of necessity, practice an intensive system of agriculture.

The accompanying picture of the twelve-colony apiary and the tile-covered beehouse of Jos. Crutzen, at Quatre Chemins (four corners), Henri-Chapelle, gives a good idea of the farmer's apiary of Belgium. The orderly arrangement and spacing of the hives, the presence of supers, with numbers to correspond with those on the hive-bodies, and the neat surroundings all indicate that attention and care are given to this secondary industry on this particular farm.

I think it is a safe prediction that the care of the bees devolves upon the good wife of Mr. Crutzen. Certainly she evinced particular interest in the picture-taking, and was so good as to write her husband's name and address in my journal.

Between Verviers, noted for its cloth-manufacturing, and

Liege, famous for the fortifications that stayed the progress of the German army in its recent invasion of Belgium, is the small town of Trooz. The route at this point is especially picturesque. The river, road, and railroad run close together in the deep valley. Near the railroad station, where we ate our luncheon on July 1, was a well-kept flower and vegetable garden which contained a small apiary belonging to an artisan who lived in a modest cottage on the slope of the hill across the highway. One might infer from the surroundings that the owner derived a large amount of pleasure and some income from his few hives of bees.

The skeps above, the box hives below, the red-tiled roof on the beehouse, the bloom of flowers, and the merry hum of the bees, produced in one, upon the spot, a sense of pleasure that description and the black and white of the photograph cannot convey.

Apiary at Trooz, Belgium.

A ride of six miles from Trooz brought us to Liege, where we remained for the night. Here we found great excitement and activity. All through the night the streets were thronged with excited people. At daybreak troops were marching through the streets; people were congregating in crowds outside the banks to obtain their money; horses were taken by the military authorities from the carts in the streets, to be led to the nearest blacksmith shop to be shod for immediate service, and automobiles were commandeered for military use. Belgian paper money was refused at places of business, and American Express checks shared a like fate at the hotels. Having learned that the Belgian Government had issued an order that no motor vehicles should leave the country, our party was particularly anxious to save its means of transportation. After a hurried conference it was decided

that a start should be made for the nearest point on the Dutch frontier in hopes that the customs official might not have received the recently issued order, and that we might succeed in getting the automobile into a country more neutral than Belgium had the appearance of being. Our run of 16.7 miles, on the morning of Aug. 1, through Visé, landed our party, baggage and car, across the border, and we congratulated ourselves that we had planned and executed well.

As I write this article I naturally recall to mind the surroundings of the orderly and well-kept apiary of Jos. Crutzen at the "four roads" of Henri-Chapelle, and that of the artisan of Trooz, and wonder whether they are still there as they were July 31, 1914, or have shared the fate of Louvain, Malines, and Tremonde.

Amherst, Mass.

A CROP OF EXQUISITE ORANGE HONEY IN FLORIDA

BY EDWIN G. BALDWIN

The orange season this year has been the most erratic that I have noted in ten years. In the first place, the bloom was very heavy. But the cold and inclement weather kept bloom back, so that it did not open evenly, and as a result it not only began late, about the first of March, slightly, but also did not yield well till end of March, and even then was very uneven. For instance, a hive on scales, here at Deland, showed only a pound or two gain for three weeks in March, and on one or two occasions it lost steadily for three or more days, owing to cold weather. We even had a slight frost on two occasions in early blooming time, while some of the bloom was out on the trees. But about the last week in March weather began to improve, and, for a wonder, the bloom held out and yielded abundantly; in fact, it has lasted till now, the 20th of April, and today the hive showed a gain of three pounds. That shows that the flow is easing off, and will be gone entirely in a few days. I can now form a pretty good estimate of the flow and of the orange season. It will be, for this locality, about half a crop, I think—perhaps more, owing to local conditions and management, condition of bees at beginning of flow, etc.; but for an average I think about fifty per cent of last year will be about right. Recall that last year was a bumper crop. My best hive this year will give about 150 lbs. as against 200 for the best hive last year. The average will not be so nearly on a par with last year, how-

ever. I find more unevenness in hives this season. The cold weather gave powerful colonies—colonies powerful early—a decided advantage that they would not have had if the season had been normal in temperature. Not long ago I remarked, in the *Review*, on the much later time of flow from orange, in California, for there April is their big month for the yield. Here I have never before seen orange yield later than April 10. This year fully one-half of our honey came in *after* the 10th! How is that for a record of ten years' comparison? Surely we never know what is in store for us. Those who had their dish right side up got a good crop—more than an average crop, perhaps, take it one year with another. Of course it is not fair to compare altogether with last year, which was very extraordinary.

One thing more I wish to note. The flow this year would fluctuate in quantity, even on days when bees seemed equally busy, more than I have ever before noted. For example, on one day the scales would show a gain of 11½ lbs. (my best one-day yield this year), and the next day it would drop to four or five; then seven, then eleven, then four, etc. I never saw it like that before, and I admit it kept me guessing. Some days I could about judge the cause. For instance, one day it might be very hot and dry, and a hot dry day shortens the flow for that particular day, because nectar dries up readily in an orange-blossom when the air

is dry. Again, when weather would be lower in temperature on any particular day I could usually note a slight drop in amount stored, though even cold weather, after bees got well into supers, did not always lower daily records, for on several cool days when I predicted a slight gain I would be surprised to note a decidedly heavy gain; but as a rule the yields kept near the temperatures. And cross? ugh! I think I have never seen bees so frantic. It seemed to them that the flow was going to stop any moment; and all readers of GLEANINGS know what a failing flow means to the tempers of the bees. Well, this whole season it has been dangerous to go near the apiary unprotected. Did I not have a hive on scales right through the flow I might be at a loss to know the reason for this show

of temper; but as it is, I can judge pretty nearly the cause, I think; for, as I said, the flow was most erratic, and so were the bees!

I have just at hand a letter from friend Galyean, of Plant City, about 100 miles further south than Deland. He says that the flow there did not begin till about April 1, and that it lasted but ten days for them there. He adds, "Orange will not probably average more than 10 lbs. per colony. I predict the poorest year since 1904 for our county" (he is speaking of Hillsboro Co., just north of Manatee).

But there is no loss without some gain; for the quality this year is the *best* I have ever seen, or, rather, tasted, or both. It is exquisite, with the emphasis on the "ex."

Deland, Fla.

A COLONY OF TWOSCORE YEARS

BY STEEN FREEMAN

This hive and colony of bees have been doing business right here for over 40 years. I do not know just how old it is, for my father purchased four colonies, and this is the only one left. It is a movable-frame hive, but the combs are so built that the frames cannot be taken out.

I have rigged it up so it takes the regular Ideal super, and I think I get an average of 20 lbs. from this old colony. The hive stands in the center of an old apiary of thirty eight-frame hives, and I expect to preserve it as long as I can.

Wamsley, Ohio.

Hive and colony forty years old.

A WINTER LOSS OF 25 PER CENT; CAUSES OF WINTER LOSSES

BY R. F. HOLTERMANN

During the last week or so I have been through the greater part of our bees, and have reports from my season's help from the rest. There is a loss of at least 25 per cent of the colonies of bees, and quite an undesirable percentage of weak colonies among those left.

Last fall in an article contributed to GLEANINGS I stated that I could not see my way with absolutely no bee pasture and upward of 800 colonies of bees to extract from the brood-chamber, the honey mixed with honey-dew. Next with the war coming on, and the difficulty of many to get hold of

what little money they had a right to, and the increasing difficulty of selling honey in our Canadian west, and some three thousand dollars' worth being left unsold for two seasons, I did not feel inclined to feed sugar syrup very heavily, running chances on the bees having a cleansing flight during the winter, and watching them for stores early. The season was very open until Dec. 1, causing the bees to consume an unusual amount of stores during the late autumn, and of them the sugar syrup went first.

I find the cause of winter loss as follows, naming the causes in the order of importance.

Dysentery—from the honey-dew in the winter food.

Starvation—owing to open fall and increased activity caused by bad stores.

Chilling—owing to the poor season and absolutely no late summer and autumn gathering by the bees, small clusters of bees perished, some starving to death, when

in another part of the hive there was abundance of honey.

Queenlessness.—Having a large number of colonies, we do not examine them in the fall for queens, and a percentage are queenless, undiscovered by us until we find the pollen-clogged combs in the hive the following spring.

At some point in our feeding, a mistake was made in the water and sugar measurements, which gave us a much thinner syrup, and, of necessity, less ripe stores for the bees. There was no way of telling how far this extended, and the only remedy lay in giving more to feeding all that had been fed, more, which I did not feel like undertaking.

If bees had wintered well, and a good honey crop had been obtained, I do not know what we should have done with our honey. Providence sometimes steps in when experts do not know when to quit booming the bee business.

Brantford, Canada.

EXPLOITS OF AN AMATEUR BEE-HUNTER

BY H. P. KIRBY

One of the most fascinating outdoor sports, if one would deem it a sport, is bee-hunting. An ideal time to begin the hunt is some bright sunshiny morning, just before fruit-bloom, when there is not much nectar and pollen for the bees to gather.

First you will need a bottle of honey and a bottle of vinegar to dilute the honey. You will need something to feed the bees from. Take an old chalk-box and put a glass slide in the place of the wooden lid. At one end place a small trough or lid to hold your honey, and bore a one-inch auger-hole at the other end in the bottom to let the bees in. A handy arrangement by which to catch the bees for the box is composed of two funnels made of wire cloth. Slip one into the other, so as to make it like a fish-net funnel, and close the small end.

You are now ready to go after them. Find some bees watering at some spring. Some on flowers will do; but if you can find some watering you can conclude that they are close by. Catch several bees in your trap. Then take them out in an open place close by and put them in your box through the auger-hole by opening the end of your catcher and thrusting it up into the hole. If they do not go up at once, darken the lower portion and then they will go up. Then darken your box by putting a cloth

over it and place it in an elevated position. Wait about three minutes for the bees to fill up. After this time has elapsed remove your cloth and slide your glass cover out. At first they will fly around and around till they get their bearings. Then they will go in a straight line to their home.

After you get their line, and plenty of bees are coming to your bait, close the box with the bees in it. Move on in the course which the bees followed. Repeat this several times, all the time keeping watch for their den in the trees. If you will place yourself in a position so that the sun will be on the opposite side of the tree you can see them very easily as they fly back and forth.

My friend and I often hunt bees, and have never failed to locate them where we found them watering. If you don't find them the first time, keep trying and finally you will succeed.

We found where bees were watering at a mountain spring about one and a half miles from home, so one bright morning we took our outfit and went after them. After we reached the place we followed the plan I have related and soon found two trees inhabited by bees. One was about a quarter of a mile from the spring, and the other about a half.

When we were ready to cut the trees the

Box hives the menace of modern beekeeping.

roads were very rough, so we just packed our things and carried them. We made two small hives, two stories high, out of half-inch lumber. Each super held four frames $5\frac{3}{8}$ inches in width, making eight frames to the hive. The bottom was nailed on, and the supers stapled together. When the weather is very warm we use a wire screen tacked on the top to give the bees plenty of air. It is very handy to have a rope to fasten around the hive at both ends; then

you can swing it over the shoulder, and that makes it very easy to carry. We took knives, saws, and other tools for transferring the combs to the frames. It takes several hours to cut the tree and to transfer the combs and bees.

After bees get accustomed to their civilized life one can remove the frames from the small hive and put them in the regular ten-frame supers.

Scottsboro, Ala.

A MEDIEVAL BOX-HIVE APIARY

BY CHARLES Y. HAKE

This picture represents an old apiary started in 1879. The shed complete, and all but the two hives in the center, date from this time. Some of them were almost too fragile to move, and required two men to handle on account of their weight in stored honey. Where these hives came apart through age, and left large openings, some of them an inch and a half in length,

the bees had them tightly closed up with glue. The hive at the extreme left, beyond the posts of the shed, was constructed on the leaf plan. The others all have crossed sticks to hold up the brood-combs, with crocks and common boxes for supers. The bees passed through a hole about $2\frac{1}{2}$ inches in diameter in the top of the hive up into the super which was set over the hole.

AUTOMATIC STIMULATIVE FEEDING

BY E. F. ATWATER

I have never been satisfied that the practice of regular frequent feeding for stimulating brood-rearing before the honey-flow is always or often profitable. However, there have been short periods when it has been highly profitable.

For most spring seasons, probably most localities furnish sufficient pollen and enough bright warm days to secure as much brood as the bees can cover and protect.

The bees of Italian blood require rather more encouragement than those of some other races in order to produce a big field force in time for an early flow. In this locality we usually secure the best results by wintering the bees in two-story hives. The upper story contains the old brood-nest, while the lower story is an extracting-super containing two to four combs partly full of honey, the remainder being empty combs.

The bees clustering in the upper story are well away from any direct drafts of cold air that may be driven into the entrance by cold winter or spring winds. During the fall, after the flow, the bees busy themselves on warm days, carrying up any unsealed honey into the combs above, where it is arranged to their liking, this activity favoring brood-rearing perhaps a little later than usual.

Then if several warm days come at any time during the winter or early spring, the bees uncap and carry up more honey, resulting in early brood-rearing. The chief benefit is in the spring, when brood-rearing is well under way and the honey in the lower body is constantly being carried above, where it may be better protected and used. If possible, it is very good practice to take heavy combs of honey from the brood-nest at this time, and put them below, giving the queen an abundance of room in empty combs in the upper story, and furnishing more honey, far from the cluster, when the bees will busy themselves

again to carry it above, all of which activity promotes brood-rearing to the utmost.

So successful has been this practice that we have felt no need of any regular feeding save in rare cases, for this plan as given above promotes activity within the hive, and with but one or two manipulations of each colony it produces as large and productive colonies as we have ever seen produced by regular feeding, and with far less labor. Even in localities where, for various reasons, the beekeeper may prefer to winter in single bodies, the above practice may be made highly profitable in the spring by taking the combs of honey from the brood-nest and putting them into a body which is to be put below the regular brood-nest. In all cases it may be advisable, especially for the beginner, to contract the entrance, so that the bees may easily repel robbers.

The well-known disposition of the bees to rear their brood near the entrance while storing their honey in the more remote parts of the hive may perhaps explain the splendid results secured by this method of automatic stimulating, as the bees wish to move the honey to the more secure position. Perhaps those using a deep bottom-board like that of Dr. C. C. Miller may secure good results by taking a comb of honey from the brood-nest and laying it on a few sticks, in the deep space of the bottom-board; but the use of a hive-body is better, as several combs of honey may be taken from the brood-nest at one time and put below. The removal of most of the honey from the brood-nest gives the bees room for more brood in a single body, where it is more compact and easily cared for during cool nights, while it is not so soon necessary for the bees to begin rearing brood in another body, with the ever-present difficulty in crossing over into another body, over about 1½ inches of top-bar, bottom-bar, and bee-space.

Meridian, Idaho.

A BUSINESS POLICY IN THE APIARY

BY JOHN W. LOVE

Not long ago, in response to a request for settlement of an account, a beekeeper promised to pay part of his bill as soon as he disposed of some trees for the sale of which he was acting as agent.

Why should he have to wait until he had sold his trees before he paid his bills? Was

his bee business so unprofitable that he had to sink into it the income from other lines of work? Or was he not allowing other lines of business to depend upon his bees not only for capital but for running expenses as well?

This is too commonly the situation with

650 lbs. of honey, W. E. Allen's December delivery. Mr. Allen, who stands beside the honey, secured 4350 lbs. from 75 colonies, spring count, increasing to 100. This was the largest yield recorded for the vicinity of New Haven, Ill. The buckets filled with comb honey accommodate travelers he meets on the road.

men who are engaged in the bee business along with other lines of work. They know they make a living, but cannot estimate the profit they receive from bees nor tell whether keeping bees pays them at all.

The farmer who has bees or the beekeeper who raises poultry should keep his accounts in such a manner that he will know whether his bees are making him a profit or a loss. If a loss, the business should be disposed of. If a profit, the business should be provided with what capital it needs, and an amount set aside for operating expenses and kept solely for the apiary.

There is this danger in engaging in two kinds of work, such as poultry-raising and beekeeping, that the owner may never learn that he is losing money in one of his lines. He may be sinking a dollar a day in his poultry, and making three a day from his bees, and conclude at the end of several years that both bees and poultry are unprofitable because neither, to his view, can make him a living by itself. On the other hand, had he known the situation he could have been deriving a comfortable living from a delightful pursuit.

A farmer gets seven cents a pound for his hogs. He thinks he is making a lot of money. Where did his feed come from? Oh! he raised that right on the farm. But raising it took labor. Now, labor costs, whether that of the farmer or the hired man. The same farmer will realize how foolish it is to maintain perambulatory corn-cribs and dispose of them for a frac-

tion of what he has put into them. If he were raising hogs and nothing else, and either buying his feed or growing what he needed, he could easily tell just how much he is making out of the business, after deducting a fair price for his own labor.

The considerations are the same with practical apiculture. The beeman can as well afford to pour sugar syrup all winter into a lot of backlot buzzers without getting any honey as to throw it into the drain. After several years of the business, if he finds he is making nothing more than wages, he might better sell the outfit to some one else, and then hire out to him as an assistant. He would be relieving himself of a lot of worry, and have his investment free for something else.

But how is the beekeeper to know whether his bee-poultry or bee-fruit or bee-farming combination is profitable, or whether his bee business alone pays anything more than wages? He can determine this only by keeping a set of accounts for his bees alone. He must carefully record every expenditure for hives or supplies and every cent he receives from a sale. He should rate his own labor at, say, twenty cents an hour if he is an amateur, and more if an expert. Then at the end of the year he will be in a position to know just how his bee business stands.

After the expenditures and labor account are deducted, if the figures show a large profit he will be wise in increasing the number of his colonies and the extent of

his operations. The point at which to stop increasing will again be shown by his figures if he has kept his accounts carefully.

Such a set of books ought to show whether the beekeeper is making any return on the capital invested. Of course, where he has only one or two hundred dollars in bees and equipment, a normal profit on the investment would not be more than a week's wages, but still an accurate set of books ought to show it. Particularly where a man is keeping bees on his own land, he is liable to forget that there is due him besides his wages something which he can call rent. He would receive rent if he let some one else use it. So rent as well as labor and some return on the equipment ought to be looked for in the final balance.

Many a beekeeper never realizes he is not making money until he finds himself

short of cash. He becomes disgusted, when perhaps at that very moment his profits are good. He is short simply because he has been running for increase or buying hives and machinery. On the other hand he may find himself with more cash than he ever had before, and pat himself on the back for his ability in the bee business. At the same time effective accounting would reveal that the outlay for new but necessary equipment will take more than he has on hand.

To go back to fundamentals, present-day competition in all lines is driving out the inefficient. The beeman with modern business methods will crowd on to the shelf his inefficient competitor. To keep his business from falling into the hands of the large commercial apiaries, the individual must be economical in his operations. Accounting is the soul of economy.

BLACKS VS. ITALIANS

BY W. C. MOLLETT

A few years ago I wrote something about the difference in the honey-gathering, hardness, and other qualities of the common brown or black bees as compared with the Italians. On page 175 I note what the editor says as to the black races of bees, and also on page 181 I notice that Mr. Doolittle says that, as to gathering nectar from basswood and clover, he has never been able to see any difference between the two races.

Now, this is a subject to which I have given a great deal of attention without making a very definite conclusion. I still have both races, and so far I cannot rate the ordinary Italians much ahead, as a great many beekeepers do.

A short time ago Dr. Miller said he thought that not many beekeepers of the present time ever saw a case of "roping" or hanging down from the comb in a rope-like cluster. I have had the blacks do this time after time, and sometimes it is a great advantage, as the bees are very easily shaken from the comb. This is usually very difficult with the Italians.

When I began keeping bees I secured a very gentle strain of Italians which were highly recommended as honey-gatherers. After I increased them to about half a dozen colonies, I thought I was sure of a fair crop of honey; but imagine my surprise when they began to swarm about the first of May, and kept it up until the season for storing honey had passed. Of course I had not had enough experience then to know how to manage them to the best advantage, or I might have secured some hon-

ey, anyhow. Since then I have learned how to manage them better; but I still feel that I do not know all there is to be learned, since I sometimes meet with surprises.

For the past five years I have had two apiaries about three miles apart—the one at home of Italians, the other of the common black variety, and so I have had a fair chance of comparing the two races. With Mr. Doolittle I find no practical difference in the honey-gathering of the two; but in other respects I find considerable difference between them. The blacks do not rear brood quite as early as the Italians, which is an advantage here, as the nectar flow is usually rather late. The blacks swarm later, and generally not until they have filled one super with honey, while the Italians will often swarm before they have worked in the supers at all. The blacks seem to economize their stores better in wintering, as I often have to feed the Italians, when the blacks, with exactly the same management, will winter without any feeding at all. As to the gentleness of the two it is a rather open question. Often I find colonies of almost pure Italians that are as cross as any bees could be. Smoking the blacks soon stops them from stinging, while I have found some Italians that were very hard to control with smoke. For color I prefer the Italians. Taking every thing into consideration I find that the Italians are often overrated. I can get just as much money from the blacks as from the Italians.

Stonecoal, W. V.

A BONANZA COLONY

BY R. J. T. MUCKLE

It may interest and encourage some beginner to see the photograph of a "Corner in Honey" in Manitoba, where "Our Lady of the Snows" is supposed to hold eternal court. The background is oak, poplar, wild

A corner in honey.

plum, and nut-hazel; the foreground, Grim's alfalfa and popcorn. The whole takes me back to Honolulu of fifteen years ago.

On May 26, 1914, I received a nucleus and queen from an advertiser, and by feeding and the switching process I had, by July 27, not only tiered up as shown, but produced and sold at \$11 each two strong swarms.

On Aug. 20 I extracted from the three center boxes 142 lbs. of a honey which our Ottawa authority, on testing a ten-pound sample, declared was the finest he had ever come across—that it was in a class of its own, and that we might put our own price on such an article. I then divided this immense colony into three heavy stocks. I fed ten pounds of sugar, made into thick syrup, to each, and, though strong for my years, being a "forty-niner" (not gold seeker but born in 1849), I found them a heavy lift to put in the cellar. They were in ten-frame hives, and weighed 76, 83, and 90 lbs. respectively.

For over 40 years an enthusiastic student of the grand cult, I have absorbed so much from various sources I cannot tell whether I learned that which I think I know from reading or experience.

Clandeboye, Manitoba.

SOME KINKS IN THE QUEEN BUSINESS

BY W. S. M'NAIR

The first queens I bought I ordered from a reliable firm, using an old price list. The price was six for \$5. They sent me three queens and an invoice at the rate of \$1.75 each. I wrote them to cancel the rest of the order, also sending a money order for the difference, 25 cts. In a week I got the three queens, according to the original order, and I had to pay \$1.75 each for these also. When I sent the money for the last three queens I asked if they did not receive my letter canceling my order, to which I got no reply. Now this was very unbusinesslike. They should have canceled my order when requested.

I ordered three golden Italian queens from a man who advertises extensively. They were untested, which means (or is supposed to mean) mated queens not kept long enough to show if they are purely mated. I also bought eight more queens from this breeder, and successfully intro-

duced nine of the total number. I have not got a colony of golden bees yet. I do not know whether or not these golden strains have become fixed in color yet; but I do know that I have some queens that were supposed to be leather-colored that are as yellow as these famous goldens. I have come to the conclusion that some queens sold as untested are tested and found mated.

The breeder of these queens wrote me that the only danger of getting cross-bred queens was from an apiary of Carniolans not far from his queen-breeding yard. As a matter of fact, all my queens were crossed with three-banded, the queens being beautiful in color, yellow to the very tip. Their offspring varied from three-banded to golden, not more than 25 per cent of each hive being golden. In one or two of them the only golden bee was the queen.

These queens also were supposed to be

gentle and good honey-gatherers. As far as that was concerned they were fair; but of course I could not judge them, since I did not get a pure one. No one can judge a strain of bees unless he manages to get properly mated queens.

This is not the worst experience I have had in buying queens. So far I got queens in exchange for my money. One time I did not. In late July, 1913, I ordered a tested Carniolan queen, and sent a money order for \$1.50. After waiting for some time I wrote and asked why I did not get the queen. As well as I can remember he said he did not have any tested, but could supply untested. I then told him to return my money. This was about November. After a week or so I received a check for one dollar on a small bank or at least a bank I never heard of before, in New Jersey. I felt pretty sore by this time over the transaction; and as I would have had to pay exchange or discount at any of our banks to have it cashed I returned the check to him and told him if he needed money bad enough to keep the 50 cts. he could also keep the dollar. I also suggested that he could send me the money in the form of an express-office order. But I suppose he needed the money, because I never heard from him again.

I am glad to say that, in my experimenting with different breeders, I have found one man who sells what he advertises. I have bought about eighteen queens from this breeder, and I could not praise his bees too highly. They are good from start to finish. The queens were all untested, and a large percentage (about fifteen out of eighteen) turned out purely mated. This is where I get all my queens in the future. It is a great thing to a man ordering through the mail to know where he can get what he pays for.

How large a number of classes queens are divided into! There are untested, selected untested, warranted, tested, selected tested, etc. It is getting to be like eggs in the grocery—strictly fresh, fresh, choice, new-laid, etc. I think this is all tommyrot.

You can't tell from the looks of a toad how far it will jump. You can tell very little about a queen until she gets started in a hive. I have seen queens that looked good which proved useless, and small-sized queens that had no beauty about them at all do good work.

To my mind there should be only three classes of queens—untested, tested, and breeders; and I believe when all is said that is all the classes there are.

Hamilton, Ontario.

WHICH IS THE PERSISTENT AND DOMINANT RACE?

BY WESLEY L. ROBERTS

I wonder if you fully realized all that is implied in the expression which you used in an editorial on page 175: "The fact that blacks seem to be the persistent and dominant race." I have studied bees by day, dreamed of them by night, and read both by night and by day. I read that the Italian bee is the bee to get, since they excel in a number of different ways. And so I have been going in for the Italian bee. I have also been led to believe, both by study and observation, that any race in its purity (speaking broadly) that excels in good qualities would be "the persistent and dominant race."

It would seem that the black or brown bee is "the persistent and dominant race" among bees. That is what you say. The proof is that all others, when left to themselves, revert to the dark type. Circumstantial evidence is added in the fact, admitted by all, that the so-called hybrids or cross-bred bees, after the first cross, show a breaking-up of all good qualities, lose their stamina, become constitutional weak-

lings, and, of course, become much more subject to disease than the pure bloods of any race.

Perhaps I have made a mistake in getting the Italian race of bees. Would it not have been better to send to Switzerland and get some of the black or brown race in their purity? The Helvetians probably have them more pure than in any other part of the earth.

Then because they are "the persistent and dominant race" in their purity they would possess much constitutional vigor, their stamina would not be broken by cross-breeding, and so they would have vigor to resist disease, the energy to gather an abundance of honey, and ability to defend it.

If I have made any mistake in getting the Italian race of bees I should like to know it as soon as possible. "The persistent and dominant race" is the race I want, because every thing in nature shows me that is where to look for improvement.

Lavalle, Wis., March 10.

[You are reading more than there is

expressed or implied in the quotation about blacks being the "persistent and dominant race." If you will read again our editorial on page 175 you will see that this "persistence" and "dominance" does not mean that these two characteristics comprise *all* the other desirable qualities in bees. And you will see, also, that we made an exception in the case of the leather-colored Italians. Note our last paragraph, second column.

The wild blackberry, for example, is "dominant" and "persistent," but these adjectives do not argue that it is the most desirable for the small-fruit grower who is engaged in the business of furnishing blackberries for the market. The cultivated varieties are vastly superior. Again, the scrub cattle of Mexico and the southern portions of the United States are, no doubt, a "persistent" and "dominant" breed of cattle; but it does not follow that in the matter of milk or beef this breed comes anywhere near the modern Jerseys or Holsteins. The point we tried to make was that black bees, for some localities, will breed up better and faster than some of the so-called yellow and extra-yellow Italians, and in some cases better than the regular leather-colored Italians; but that does not follow that the black bees of Virginia will be the equal of a strong and

vigorous strain of Italians, either for honey production or resistance to disease for Virginia or elsewhere. As a matter of fact, blacks do not resist foul brood like the yellow bees.

The tendency of nature is to revert back to the original; but it does not follow, nor have the facts proven, that a pure strain of Italians where there are no blacks will in time degenerate to black bees. When we speak of black bees or brown bees it is proper to say that either Carniolans or Caucasians or Banats are their superior in almost every respect. In some cases they may be better than leather-colored Italians; but our experience, covering an extended observation and travel all over the United States, leads us to believe that the ordinary Italians that have not been run for color are superior to any other strain of bees, although an exception should be noted in certain localities. The fact that Italians have the preference on the part of about 90 per cent of all the beekeepers in this country would seem to indicate that even if they are not the "persistent" and "dominant" race of the world they are superior, from the standpoint of dollars and cents, and convenience and ease in handling; yet there are certain localities where we might prefer Carniolans or Caucasians; but these localities are very limited.—ED.]

AN APIARY OF 250 COLONIES WINTERS SUCCESSFULLY ON ASTER HONEY

BY J. L. BYER

The first time I remember hearing of bad effects of aster honey was at the Denver convention some years ago, when the Manley Brothers, of Sandusky, Mich., stated that in their section the late honey always proved fatal to the bees, and as a result they did not try to winter the bees any more, preferring to take all the honey away and buy more bees next spring. Many of us thought it a wasteful plan, to say the least, and we all had our idea as to how *we* would do under like circumstances. The most popular plan advocated was to extract all the late honey from the brood-nests and then feed sugar syrup; but, like some other things advocated, it is easier sometimes to tell *how* to do a thing than to do it.

Since that time we had almost forgotten what we heard about aster honey, as in our locality we never had any of it. But last fall at the yard 100 miles north of Toronto we unexpectedly got a flow of this honey

in September, and then again aster honey became a live topic. There were 250 colonies in the yard; and while clover had been a failure, during August we got a flow from thistles, willow-herb, etc., of about 50 pounds per colony. During August I sent up 2500 pounds of sugar, thinking that much or more would be needed as among the 250 colonies one hundred were in eight-frame L. hives, and, as all know, when running bees in hives as small as that for extracted honey, as a rule there will be light brood-nests in the fall when supers are taken off. Honey was taken off during the first week in September, and all supers stored in the sheds. About Sept. 10 the weather turned very warm, and the millions of small blue asters growing on the uplands, that we had hardly noticed, began to yield honey. For twelve days this hot weather continued, and honey came in quite freely. We saw at once that some of the strongest

The bees appeared lively and healthy in every way.

colonies in the eight-frame hives would have to be given room, and a single full-depth super was given to about 60 colonies.

Over 1000 pounds of honey of light color, light body, and rather indifferent flavor, was extracted, while of course all the other colonies without supers—nearly 200 of them, simply jammed the brood-nests solid. We had aster honey for once—no doubt about it—and now it was high time to put into practice some of the suggestions we had so freely offered Manley Brothers at Detroit. But (let me emphasize the word) when we looked at that big yard with solid combs, the weather chilly most of the time, and bees quite stupid, the idea of tearing out all those combs from the brood-nests did not look a bit fascinating; in fact, it was almost an impossibility, all things considered, and I began to see why bees were left alone with late stores, even if they stood a good chance of dying before spring. They managed to feed 700 pounds of sugar to the 100 eight-frame Langstroth hives, but no more would they take, even when inverted pails were left over them for two days. The other 150 colonies had much deeper frames, and feeding was not to be thought of. So, after all we had said on the question previously, the bees were left to winter on aster honey, and in a locality where the mercury often crawls to 30 below zero F., and once in a while to 40°.

During the past winter, reports from aster honey as a winter food gave us but little comfort; and during all the season, including this spring, I have seen only an isolated case or two where success was reported, and then the bees had flights in February. We are all familiar how the bees of the Root Co. acted. Although wintering in a model cellar, they had to be carried out for a midwinter flight. So good an authority from so far south as West Virginia, Mr. L. H. Robey, wrote me that they often have trouble with aster honey. It sours in the hive, and if the bees are confined very long it is sure to cause dysentery. He said he felt quite sure that, if his bees had no flights from late November till February, they would die if wintering on this honey. As we have some of Mr. Robey's bees at this yard, of course his experience did not encourage us very much.

The bees at the yard in question had no flight after the last week in October. December was the severest on record—much the coldest month of the winter. The nearest tested thermometer registered 42° below on Christmas day; but at that time the hives were pretty well buried with snow. As March came in, a day warm enough for bees to fly was patiently waited for; and as the month began to draw to a close without such a day, I am afraid that I began to be a bit impatient sometimes. Our bees in

About a foot of snow lay under the trees.

York County had several partial flights during the bright days of March; but the temperature rarely got much above the freezing-point in the shade, although the month as a whole was delightful. A good friend in Orillia, Mr. Bruce Murphy, a manufacturing jeweler who keeps a few bees as a side issue, very kindly wrote me frequently as to the weather up there; and as he is only fifteen miles from our bees I felt sure that his local conditions would be similar to what they would be at our apiary.

To make a long story short, the bees up there had no flight until April 7, when the weather turned warm. On the next day I took the train and went up to see how bad the wreck was. The bees had been closely confined for over five months. Arriving at the destination about 1 P. M., and getting a key at a neighbor's, I started to walk through the bush south of the apiary. About a foot of snow was still among the trees, as can be seen in the distance at the left-hand corner of one of the pictures. The day was warm—fully 60 in the shade; and as I heard the roar of bees I knew they were not *all* dead, anyway. As I approached the yard I squinted through the trees when within sight of the apiary, expecting to see the smeary marks of dysentery around entrances of the cases. As I got a bit closer, sure enough there were dark colors there all right; but as I got closer

still, I saw that the coloring was bees, which seemed to lie by the hundreds around every entrance. I soon found that they were robbing out two colonies that had died from queenlessness, and of course the bees were guarding their entrances. But I assure you that, after not seeing the bees for so long, the tremendous roar of the thousands of bees in the air was the sweetest music I had heard for some time.

A rapid but by no means thorough examination that afternoon and the next forenoon revealed the following facts: Not a spot of dysentery in the whole apiary, the bees appeared lively and healthy in every way. Out of the 250, probably ten or twelve were dead. I suspect all had been queenless last fall, as the few I looked into had no bees, and had solid combs of honey. Roughly speaking, 200 appeared to be strong while about forty were weak. A lot of swarming in August, no doubt, left some weak colonies last fall; and during the flow in September there was little brood, and field bees would be worn out. That would mean weaker colonies than under ordinary conditions. Bees were heavy with stores, and they seemed to have used little for wintering. Stores were in excellent condition; and in the queenless colonies mentioned, some unsealed aster honey was at the bottom of combs, thin and watery, but not fermented. Of course I was gratified; and while too early to whistle very

much, it seems certain that aster honey in this case was not bad for wintering. The honey was gathered during very warm weather, and bees were packed early in October. That may have helped.

Is there a possibility that different kinds of aster vary in the matter of quality of

honey? Although much of the larger kind with blue blossoms, growing in low lands, was present, yet no bees touched them. They swarmed on the smaller blue variety growing on the uplands. I don't know why such difference between here and Ohio and other places. Can any one enlighten us?

BEE VALUES AND SOME QUESTIONS

BY FRED E. WHITE

I have been asked "What is the value of a hive of bees?" so frequently that it has become desirable to have a ready answer; and to that end I have been figuring as follows: Local values are—bees, \$3.00 to \$5.00 (swarms or in boxes); ten-frame L. hive with full sheets of foundation, \$4.20 (medium brood, 12½ cents per sheet).

This combination might prove satisfactory for the summer months, and so might the price (\$8.50 roughly); but what about early spring when folks generally feel the lure of the land, and are searching for "ways and means"?

At this time, as I understand it, a hive must be complete, and that would mean adding to the above figure the value of the drawn comb, which would be about \$5.00 extra, and the price of the 35 or 40 lbs. of honey left in the hive for winter feed, say \$6.00 (honey retails here at 17½ to 20 cts. per lb.).

There is yet another item that should be recorded; viz., the winter losses. These should be averaged, and the results added. These figures bring the total up to about \$20.00.

I do not think one would make many sales at this price, as the old box hive at \$5.00 looks more attractive.

1. Wherein can these figures be reduced?
2. How early in spring can bees be satisfactorily transferred to foundation?
3. If swarming is discouraged and divid-

ing practiced, can one sell bees in early spring without combs?

4. What does your experience in selling bees by weight suggest in this connection?

5. What is the accepted value of a frame of Langstroth worker comb?

6. Is a honey-flow necessary to make bees draw out foundation?

Bees at \$5.00 in the spring and winter, feed at \$6.00, as above, does not look like good business, especially in view of possible winter losses; but, unfortunately(?) bees are not to be had in large quantities here, and so it would not pay to destroy them in the fall and sell the honey. Perhaps the better way would be to winter them on sugar syrup.

North Vancouver, B. C.

[2, 6. It is almost impossible to give a definite time, owing to changeable weather. Usually not until fairly settled warm weather can be expected. If the bees are fed syrup a honey-flow is not a necessity.

3, 4. Selling bees by the pound before June 1 is a pretty expensive proposition, as we know by experience.

1, 5. It seems to us that most of your figures are pretty high. In the spring there would not be 30 to 40 pounds of honey in the combs, ordinarily. Again, it is possible to buy drawn combs, frames and all, for 25 to 35 cts. apiece. If \$3.00, say, were added, the cost of the frames and full sheets of foundation should be deducted from the cost of the hive in the first place.—Ed.]

COST OF RUNNING AN AUTOMOBILE

BY HARRIS T. KILLE

According to the experience of U. T. Cox, given in the March 6th issue of the *Rural New-Yorker*, the editor's estimate of 10 cents a mile as the cost of running an auto truck is none too high. Mr. Cox used an auto truck with a rated capacity of 1500 lbs. He lived seven miles from market, and used it for hauling fruit. Concerning the cost he writes as follows: "The truck cost

\$750, and has made about 750 trips or more the past three years. It is about worn out, though it would have lasted much longer with better care, and had been used on good roads, so it has cost about \$1.00 per load in wear and tear of the machine, and operating expenses and repairs in that time cost about 75 cents more, or \$1.75 per round trip." The round trip in this case was 14

miles, so the running expenses were 12½ cents per mile.

Twelve and a half or even ten cents a mile may look appalling to the average beekeeper, simply because he has never figured the cost of keeping a horse. Even if it were true that the mileage cost of traveling or hauling by auto truck exceeded many times that of doing the same work with horse power, it does not necessarily prove that the horse is the more economical means of transportation for the beekeeper. Time is money, and no one will deny the fact that the auto saves time. Mr. Cox was able to save at least three hours a trip in hauling his fruit to market. If we value his time at 25 cents an hour (and if he is much of a farmer he will be insulted at such a low valuation) he saved 75 cents' worth of time a trip—enough to pay operating expenses and repairs.

Beekeepers seem to be either disinclined or unable to get hired help. The time that the apiarist can expend among the bees largely determines the size of his income.

So the profit of an automobile should be estimated from the extra hours it will enable the beekeeper to be among the bees doing profitable work.

I should like to see the cost of running autos discussed further in the columns of GLEANINGS. I think Mr. A. W. Smith, pages 122-123, Feb. 1, was rather fortunate in getting an extra good car at an extremely low price. The average beekeeper may not be able to duplicate his results. I wish he had told how he fixed his Ford so that he could carry loads of hives, and how heavy loads he was able to take safely at a trip. May we not have more articles and photos dealing with the auto for the beekeeper? Let us have original cost, period of usefulness, cost of running, method of building carrying body, time saved, etc.

The auto is, I believe, destined more than any thing else to make beekeeping an industry for the specialist. Surely it will enable us to follow Hutchinson's advice to "keep more bees."

Swedesboro, N. J.

A GRANULATED DEPOSIT OF HONEY-DEW

BY ALVIN L. HEIM

Honey-dew is deposited on olive leaves by the black scale, which causes fruit and branches to grow sticky when it is warm.

Crystallized honey-dew on olive leaves.

I think the granulation of the honey-dew was caused by a rain some time ago. The deposits dissolved, and the consequent evaporation of the waterdrops left the deposit as shown. The bees worked on it during the early summer last year, but not much after the blue curl began yielding nectar.

The honey crop in the alfalfa and carpet-grass regions of this state last year was very poor, and the market in honey is even poorer. The outlook is "blue."

Fairoaks, Cal.

The Irresistible Call

BY GRACE ALLEN

The year with his ancient enticings
Is tempting the summer to come;
The trees are in leaf and the lilac in bloom,
And the bees are beginning to hum.

Spring's daffodils down in the corner
In tarnished gold wither and waste,
And the purple-blue iris is flaunting her flag
To signal the summer to haste.

She might have resisted the blossoms
Or singing of birds in the trees,
But she'll come—oh! she'll come on a wind from
the south

When she hears the old hum of the bees!

Aster Honey—Its Quality and Color

Can you give me some reliable information regarding aster honey? I wish to know of the color and quality. I read an article by a correspondent of GLEANINGS some time ago in which aster honey is described as light in color. Dr. Phillips questions this statement, and I had always believed that aster is a dark honey, though we get none here except such as is mixed with other honeys.

As you handle so much honey from so many different localities I thought that you might have seen samples sufficiently pure to enable you to inform me in regard to this particular point.

Athletic, Iowa.

FRANK C. PELLETT.

[The name "aster," when referring to a certain honey, covers a multitude of sins. There are some aster honeys that are comparatively light in color, and not bad in flavor; but most of the asters that we have tasted and marked as such are on the light-amber order, and lacking body. Some would call the flavors comparatively good, while others would call them poor. Any one who has been educated to the use of clover honey, alfalfa, or mountain sage, would call the aster flavor poor; but others who have been educated to eat aster honey might call it of good quality. For example, a great many people who live in New York like the buckwheat flavor because they have been brought up to eat it from childhood. But most people outside of that state would prefer almost any other flavor to buckwheat.]

To answer your question more explicitly, we may say that the general markets do not class aster as a table honey. While it would hardly rank in flavor with most of the amber honeys, it is lighter in color than the average of the ambers.—Ed.]

Why Aster Honey Makes Trouble Sometimes and Not Others

It is noteworthy that most of those beekeepers who report bad results from using aster honey as a winter food place their hives in cellars; while those who have found it without objection winter largely outdoors. From this it is clear that aster honey under proper conditions must be wholesome and harmless, since if it were deleterious in itself there would be uniformly bad results.

Aster honey is open to two objections. First, it crystallizes quickly, and at times in such a hard form that it is partially unavailable. Thus occasionally bees may starve with an abundance of candied aster honey in the hive. Second, aster honey is gathered so late that winter may begin before it has been properly ripened and sealed. If the hives have been placed in a warm damp cellar the honey may easily deteriorate or spoil, producing dysentery among the bees; but probably any other honey stored equally late, and not fully ripened, would do the same. There has not yet been a particle of evidence offered to show that the chemical constituents of aster honey are in any way injurious to bees or human beings. On the contrary, it is an excellent table honey, and hundreds of colonies of bees have wintered on it with very small loss. No doubt it is often blamed for failures that are due to other causes which the beekeeper has failed to perceive.

JOHN H. LOVELL.

Waldoboro, Maine.

What is Squash Honey?

Mr. Newell, page 647, Aug. 15, 1914, under the heading "Squash Honey," says of my communication on page 433, June 1, "If you can believe your botany all alders bloom in spring. To controvert this assertion I may be pardoned for mentioning what I find in Prof. Gray's School Botany, as many readers of GLEANINGS do not possess a botanical work, nor understand that common names of plants are not distinctive. He chooses to use the common name that would be misleading to some."

Gray's Botany, page 217, Sec. 19: *Clethra*, white alder (old Greek name of *Alder*, from some resemblance in the foliage). Flowers in summer. *C. alnifolia*, the only common species, in low ground three to ten feet high, with wedge-obovate sharply serrate, straight-veined leaves, and upright panicle racemes of fragrant small flowers."

Mr. Newell also says: "Our fall honey all comes from squash-blossoms." For many years my bees have collected quite a lot of goldenrod honey, depending on conditions of weather.

Further on he says, "If you know anything about squashes you know the blossom is open only one day." Having made a specialty of melons until I was 67 years old, I know that squashes and cucumbers have the pistillate and staminate in distinct blossoms, the staminate appearing some time before the pistillate, and very much more numerous, and holding more than one day, while the pistillate will close very soon after it is fertilized; but if not fertilized it may hold for more than one day; but as the bees are always numerous on them they are very likely to be fertilized the first day.

Bees work on many flowers which give only pollen; and in my opinion that is why they work squash and cucumbers. Dr. Miller has said in some of his

writings that there was a pickle-factory at Marengo, and an extensive field of cucumbers, but he did not know what cucumber honey is.

Until fourteen years ago, in the neighborhood where I lived melons were cultivated extensively for the Lowell and Nashua market, and I always had bees. Yet I don't know what melon honey is. I think it is principally pollen that the bees get out of their blossoms.

Woburn, Mass.

JOHN P. COBURN.

[We believe our correspondent is in error in believing that bees do not get nectar from squash-blossoms. See A B C and Z Y Z of Bee Culture, page 360. "Nectar abundant in a little reservoir at the bottom of the flower."—ED.]

Making Increase with a Pound of Bees and a Strong Colony

With one strong colony of hybrids in one hive and half a pound of Italians, with breeding queen, in another, how would you proceed to get the greatest possible increase in one season? WISCONSIN.

[In the first place we would draw a frame of hatching brood from the strong colony, giving it a slight shake to jar off the old bees. The young bees will cling to the frame. Give this to the pound of bees. As soon as the brood has hatched, or the larger part of it at least, give another frame of hatching brood as before. Give it a slight shake before doing so. Continue thus to draw on the strong colony till both are of about equal strength. From that time on, increase can be secured by any of the well-recognized methods given in the text-books. Queens should be reared from the breeding queen; and as fast as the nuclei are made they should be given a cell or a virgin queen from the breeder.

At the very beginning of things all drone brood in the hybrid colony should be uncapped and beheaded, and a drone-trap attached to the entrance to catch the flying drones.

As soon as it is practicable, a cell or a virgin from the breeder should be given to the hybrid. After increase is well under way, give the breeding queen to a nucleus. It is always desirable to keep a breeder down so she will not exhaust herself by continual egg-laying. If she is kept in a nucleus of one or two frames she will furnish all the eggs for grafting or cell-building that will be required.—ED.]

Some Questions on Queen Introduction

I am having considerable trouble getting the bees to stay in twin mating boxes. I have set out so far about 100 boxes, giving each a feeder of thick honey, a day-old virgin, and a pint dipper of bees. The bees seem to drift or abscond from some of them by degrees.

In thinking the matter over, it seems to me that my mistake must be in using too young a virgin without any brood. At any rate I shall give the next bunch about a five-day-old virgin, as an experiment. I do not see how bees can be made to stay on dry comb for ten days. Please advise if this is my mistake.

How old can a virgin be before introduction is made, and still be reasonably sure of mating?

In this country every thing has to be protected from heat, and I have set the boxes out under shade-trees, four on a stand.

We still have 200 of these boxes, or 400 nuclei, to set out, and you will realize that, bees and all, it is quite an investment.

How old should a virgin be for smoke introduction? I used three-day-olds last fall, and very little smoke, but find a lot of drone-layers this spring. This locality is extremely peculiar in that virgins seem to remain soft, pale, and distended between two and four days after hatching on account of

heat, and are a very bright yellow after mating, and until shipped elsewhere, when they assume natural shade.

I do not believe it safe to introduce by smoke here with the queen less than five days old—may be not at all when it gets hot. It averages 105 to 110 in the shade here during July and August.

Overtown, Nev., April 2.

T. W. RIGGS.

[Mr. Mell Pritchard, our queen-breeder, replies:]

We prepare our boxes by opening the ventilators and closing the entrances, filling the feeders with very thick sugar syrup, and putting in one dry drawn frame on each side. We next drop in a virgin, and pour in about $\frac{1}{4}$ lb. of wet bees on each side; close up the covers, and set the boxes in a cool shady place, leaving them there until late in the afternoon of the following day, when they are placed on the stands, and are released before sunrise the next morning. By this time the feed has all been taken out of the feeder and put in the one frame. After the bees have had a fly and settled down we put in the other frame on the side next to the division-board. The queen will lay in this frame, and the brood is the warmest part of the box. We prefer virgins about two days old; but virgins introduced at four days old probably make just as good queens. We would not use them much older than that.

Our boxes are on individual stands, in rows 15 feet apart each way. We have tried putting them closer, but find too many queens are lost at mating time. Our boxes are in the shade. With a temperature of 100 the frames would surely melt down if they were not shaded.

Transferring Made Easy

In transferring from box hives I simply made a frame out of half-inch stuff which would cover a ten-frame hive-body. This frame had a square hole in the center, about 8 x 12 inches. I laid this over the new hive, then took off the bottom of the old box containing the bees, and set the box (bees and all) over the new hive. After stopping the entrances to the old box I pried off the lid or cover, and with a little smoke drove most of the bees off from the combs into the new hive. Starting on one side I began cutting out the old combs. When I came to the brood I filled two or three frames with this, and put it in the new hive.

I transferred ten hives of them in February in this way, and about the 10th of March I had to put on supers, having saved every one of the queens. They went right to work in their new quarters.

This method, I find, saves most of the muss one makes by the old way as described in the A B C and X Y Z. Besides, there are practically no bees flying about to bother. What little honey there is dripping around is in the new hive. They soon clean this up and store it in their own hive.

Willowbrook, Cal.

F. E. DUTCHER.

Two Queens Wintered in the Same Hive

I have a queen I purchased two years ago. Last summer the bees seemed to want to start cells to supersede her. I let one of the cells hatch out with her. Last fall I found the young queen laying, and the old mother queen, which was clipped, on the same comb to-day. I opened the hive and found both queens, the old queen laying, but the young one on the outside comb in perfect condition, but not laying. She is a nice large queen, larger-looking than the mother. I never knew two queens to winter in one hive loose together this way before. I am very sure the young queen was laying last fall, and am sure the old queen is laying now.

A. I. Root

OUR HOMES

Editor

Trust in the Lord, and do good; so shalt thou dwell in the land, and verily thou shalt be fed.—PSALM 37:3.

I have been young, and now am old; yet have I not seen the righteous forsaken, nor his seed begging bread.—PSALM 37:25.

When any one comes to me for advice, especially when any boy or girl wants the benefit of my experience in times past, as a rule I am ready to respond at once; but below is a letter received some two months ago. In this case I have delayed answering because I wanted to consider the matter well, and possibly get some light from some of the various periodicals which it is my pleasure to review more or less every day of my life. Besides, I have been praying that God would give me wisdom and understanding as I consider our young friend's troubles. Here is the letter:

Mr. Root:—I am a boy eighteen years old, belonging to a family of ten. All but one are younger than myself. Mr. H. H. Kolloster, who is a neighbor to us, called my attention to an article in your journal in which you make answer to letters he has written you. He informed my father and myself that he had used our case as an illustration of the unemployed. It has been some two years since I first met Mr. Kolloster. As he seemed quite intelligent in his talk I decided he could give me the information desired. At that time I had a great desire to join the army, as the Government advertised they would teach the soldier a trade, and that was just what I wanted. So I asked him how I could join the army and become a soldier. Imagine my surprise when he asked me what foreign working man had offended me that I should want to kill him. I explained I had no desire to kill any one. I wanted to learn a trade, and in this way I could do so. Again he said, "Find me a soldier who returned from the army who had learned a trade there, other than *murder*. Go home and take your Bible and read, 'Thou shalt not kill.' God meant that when he said it; and when you become a soldier you are given a rifle, a sword, and revolver, and you are taught how to use them, and you kill people whom you never saw and who never harmed you, just because somebody who is your boss tells you to; and the more you kill, the bigger hero you are. A battle-ship is a very large machine. It takes from seven hundred to one thousand men to run it, and its use is for no other purpose than to murder people; therefore it is a murdering-machine, the best that man can make."

Mr. Root, your sour-faced friend changed my mind. Was he right? I joined the Boy Scouts then, and later informed my friend that I had chosen something better than the army. He pleasantly drew a word picture connecting the boy scouts with the army, and my peace of mind was again disturbed. I disbelieved him, but the picture he drew was so forceful that I dropped the boy scouts. Now, Mr. Root, would you have advised me as he did?

I was born in Belgium. My poor old grandfather was stripped of every thing he had in this world, and was forced from his own native land into a foreign country, and other relatives missing, there to accept charity. The picture my native country presents to me causes me to think of soldiers and

murders, and the boy scouts are found there as soldiers.

Here is one problem Mr. Kolloster has never been able to solve for me, and it is the sole object of this letter. I am eager to learn a trade. How can I do it? If you can solve this problem for me you can do me a world of good. I am quick and easy to learn, and ambitious, orderly, and obedient. Here is my problem: Two years ago, on account of sickness in our family, it fell to me to support this family of ten on \$1.25 a day of 12 to 13 hours. At the end of eighteen months, with my father barely strong enough to be around, I was informed by my doctor that if I did not quit work at the mills I could not last long. After doctoring a month I worked for Mr. Kolloster for two months, building houses. He has not had a contract since, and I have not been able to get more than a day or two of work at a time, and the family is supported by the children who are able to do a little each week to help catch the nickels. I am just now filling the only place offered, that of messenger boy at ten dollars a month, and board myself. When you solve this problem, please send it to me. I would inclose a stamp, but you see what chance I have of getting it. Our streets are full of men out of work.

I will give you some points that Mr. Kolloster has taught me since I have known him. He says that under socialism all children would be educated, and learn the trade they would like to learn until they are twenty-one years of age, at the expense of the whole people, text-books and board included. Don't you think that would be all right? He says that after twenty-one years all men and women would be paid by the whole people the full value of the product of their toil less the expense of running the industry, and every man and woman guaranteed a job. Is that wrong? He says all the things publicly used would be publicly owned, and why not? He says there would be no profit and no interest, and he that won't work shall not eat.

Palatka, Fla., Feb. 14.

JOHN GIBBON.

My good friend, I am glad to know that your neighbor asked you to turn to your *Bible*; but I regret that he did not at the same time ask you to present your troubles to the good pastor of your church. I take it that you go to Sunday-school and Endeavor society.* I greatly fear, however, that you do not. I would also advise you to talk with the superintendent of the Sunday-school. He certainly should be able to give you *some* needed advice. Your letter has done me good, because it has set me to thinking, and to talking with good and wise people. Perhaps I have been in times past a little bit too vehement in denouncing war and warlike instruments. You may, perhaps, be aware that there are some religious denominations that call themselves "Non-resistants." They will not go to war nor will they go to law. I knew quite intimate-

* A judge in Brooklyn (one of Frank L. Brown's old Sunday-school boys, by the way) says he has sentenced over twenty-six thousand juvenile criminals; but among them all was not a single Sunday-school boy or girl.—*Sunday School Times*.

ly one such old gentleman who was a bee-keeper. This beekeeping friend had a lovely daughter. A bright-looking chap, an entire stranger, got his eye on the girl and made love to her. Her father remonstrated; but as he was a non-resistant he did not make any great fuss over the matter. This slick young chap deliberately ruined the girl and left her. The father would do nothing, because he did not *believe in going to law*. Her own brother told me that his father, on account of his foolish religious principles, let this young reprobate go off "seot free," to ruin some other girl in the same way.

My young friend, you cannot remember, but I can, when John Morgan's band of guerillas invaded Ohio. They crossed the Ohio River, ransacked the stores, and robbed the banks; and they would have kept on going all over Ohio had there not been some men (and boys) who knew how to shoot. Had you and your good neighbor whom you have quoted been present in such an event, would you have permitted those guerillas to go on with their work simply because the Bible says, "Thou shalt not kill"? Suppose all of our great cities were to be suddenly deprived of policemen, or, let us say, the policemen to be deprived of their revolvers and other implements of warfare, what would be the result? In the city of Cleveland, murders, holdups, etc., are so common that petitions are being circulated to double the number of police. Occasionally a pickpocket, burglar, or highway robber overmasters a policeman. Every little while we read of one who loses his life in a righteous attempt to preserve peace. We hope and pray that *rebellion* will never break out again in the United States. But suppose it does; and suppose some foreign nation should discover some vulnerable point in our borders in some poorly protected point, and a call for soldiers were made to protect "our native land," what would *you* do? Washington has been revered and held up as the father of this country, and as a model man ever since he died, and yet *he* was a fighting man.

Now a word about our military schools. A young friend of mine—yes, quite a near relative—lost both father and mother away off in California. I feel sure he will excuse me, under the circumstances, if I mention that he had contracted some bad habits. He was inclined to be unruly; and as he did not seem to get along very well he took a sudden notion that he would enlist. He got a situation on a battle-ship. Now, it was one of my happy surprises to see that the boy

has been straightened out and literally "made over" in the course of two or three years. He had good sense enough, thank God, to realize the importance of *obeying orders* when those orders came from Uncle Sam. In a short time he was promoted for good behavior. Just a few days ago he wrote me that he would give almost any thing in the world to have me hear a good minister, with whom he was acquainted, preach. I might give an extract from that letter that caused me to thank God, but I sent it to the good pastor to encourage him in his faithful ministry. Among other things, this relative wrote me that, when the men on board his ship touched the shore, they seemed to think that they were for the time being free from restraint, and a good many of them returned under the influence of drink. At the time of his promotion he was particularly commended because, no matter how long a leave of absence he had, he always returned clean and sober. With such a man as Daniels at the head of the navy we have a different state of affairs from what there was in former times.

Now, my good friend, here is another phase of the matter: You and your neighbor seem to think that you are "handicapped." What you are compelled to pass through is not particularly different from what thousands of other boys, and especially young boys, have passed through, who have in the end "made good." Our great men in all walks of life started out under straitened circumstances, as a rule—if any thing, much *worse* than yours. But they did not sit down nor give up and lament over their "misfortune." That you may know that there are good people who are considering this very question of a military education, I give below a letter from a good woman in much the same line.

Mr. Root:—Will you kindly give in your paper a reply to a question which has troubled me, and no doubt others, for a long time? But before I put the question I want to say that your highly valued paper has been in my mother's home for a number of years, and is considered to be the best periodical which enters the home because of its Christian character and sterling worth. Being a frequent visitor at home I have derived much good from the perusal of your articles, and so in a way I feel myself a member of your great family of readers, and believe you will consider me so.

Now as to the question. We read your article about toys, guns, firearms, etc., and we should like to ask why it is that, if America is such a *peace-loving* nation, it permits and encourages its young men to become so familiar with military practices and guns as it does in the A. and M. Colleges all over our land? Why will it not allow a young man to study agriculture without also forcing him to take a military training for five years, as is the custom here in Oklahoma, any way? This means much to me. I have an *only* son who has attended the A. and M. College at Stillwater for three years;

and as a peace-loving citizen I have often been troubled about the encouragement given to war.

Last year, when there seemed to be a likelihood of war with Mexico, a number of names of young men likely to be good soldiers was sent in to Washington by the commandant. I am almost certain my son's name was sent along, as they had advanced him rapidly. In consequence I have some objections to his returning to the A. and M., and yet I am anxious for my son to get a practical agricultural training. It is true the discipline in a way is good for the students; but could not that be secured in some other way?

I am sure there are others as vitally interested in the study of this question as myself, and for their sakes, as well as my own, would be pleased to get your view on this matter.

MRS. ROBT. BROEGELMANN.

Ringwood, Okla., Nov. 23.

Since reading the above letter, another incident occurs to me. Just a few days ago a business man in some city became suddenly insane. He shot, or shot at, everybody in sight in the office, then rushed out into the street and began to kill people right and left. Before a policeman could be found who was a practiced marksman this man had maimed or killed toward a dozen persons; and nobody knows how many more would have been killed or maimed had not a quick bullet from the expert policeman wound up his career. While it is not at all necessary that every young man should become expert in the use of firearms, at the present stage of the world's history it is exceedingly important that at least a few persons in a community should know how to save human life and perhaps protect property.

Now last, but by no means least, I have some good news for the young friend who writes the above letter, and for every other bright young boy in the whole wide world. I want to introduce you to the "champion corn boy of the United States;" and I do it by making a clipping from that excellent home journal, the *Ohio Farmer*, of April 19.

CHAMPION CORN BOY OF THE UNITED STATES.

Did you ever hear of Walker Lee Dunson? Well, he is the boy who astonished the world in 1913 by raising 232.5 bushels of shelled corn on an acre of ground. The total cost of this enormous yield of corn was only \$46.40, or a total of 19 cents a bushel. This was not the first time Dunson has won the prize for the largest yield of corn in the state where he lives, for in 1912 he grew 172 bushels at a total cost of \$35. As if to prove that it was not a matter of chance that he won twice, he again won the highest yield for his state in 1914, making the third time he has carried off the high honors and also making the highest official yield of any boy in the United States.

In January I went to Alexander City, Alabama, and inquired where Dunson lived. It was ten and a half miles out in the country over muddy roads. On the way to this farm I noticed that the land was very stony; the hills were steep, and covered with jack pines, scrub oak, broom sedge, and deep erosions. From appearance it was the last place on earth one would look for a champion crop yield of

the United States. After arriving at the farm I found Walker Dunson a very much younger boy than my fancy had pictured. He was 15 years old the 4th of last December, so that will make him eligible for several more corn-growing contests. The average yield of corn in Alabama is only 17 bushels, yet the 3358 boys in the corn-growing contest made an average yield of 48.3 bushels per acre, which beat the other corn-growers by 31.3 bushels an acre.

The corn grown by the boys was made at an average cost of 26 cents a bushel, while that of the average farmer cost 70 cents. The location of the field where this high yield of corn was grown was very interesting to me. It is located in the valley between two very steep hills, and the dew settles in the valley and furnishes considerable extra moisture to the corn crop in the dry summer weather. This was the only special advantage of the location except that the valley is naturally somewhat richer than the upland. The soil was a sandy clay loam with more sand than clay. There was a splendid stream of water in the valley, and Dunson had intended to water his corn with a gas-engine and hose, but was prevented by the Department of Agriculture, as they ruled this an unequal advantage. No exception was taken, however, to the unusual amount of commercial fertilizer that was used. This field had 2300 lbs. of a 10-4-4 fertilizer but no barnyard manure.

After asking Dunson for his picture I was surprised to learn that a camera had never been to visit his place. Then I sent a telegram to Chicago and had an expert photographer start immediately for his place, and the pictures in this issue are the result. For the last two years one of the railroads has offered a fine four-year-old registered Percheron mare for the highest yield of crops on what is known as the four-crop contest. Mr. Dunson won these fine Percheron mares both years. His four crops made the following: 175 bushels of corn, 1623 pounds of cotton, 1974 pounds of peavine hay, and 3354 pounds of oats in straw. The total profit from these crops was \$212.67, with an average profit of \$53.17 to each crop. As Dunson had only three acres under cultivation he made an average profit of \$70.85 an acre.

In addition to the horses, Walker Dunson has won a \$250 scholarship to the State Agricultural College. He has also had a trip to his state fair and the national capitol at Washington, and cash prize of \$50 besides. Perhaps the most interesting part of it all is that he has made the following records in the last three years: In 1912 a yield of 172 bushels of corn at a cost of \$26, or 15 cents a bushel; in 1913 he made 232.5 bushels at a cost of \$46.40, or 19 cents a bushel; in 1914 he made a yield of 175.5 bushels at a total cost of \$35, or 20 cents a bushel. He has made a grand total of 579.75 bushels of corn in the last three years, winning every year, with a total cost of \$107.40, and leaving him a total profit of \$471.85 from the corn alone at the market price. The average cost of growing this corn was 18 cents a bushel. However, Dunson really made more than this from his corn, as most of it was sold for seed at \$2.50 and \$3.50 a bushel instead of selling at the market price.

Dunson cultivated his corn ten times last year. This was done every ten days unless there was a heavy rain, and then it was cultivated as soon as he could get on the field to work. He says he will not rest on his laurels, but intends to enter the contest again.

He plants the Marlboro Prolific corn, and has his seed all saved in good shape from stalks that have three and four ears on the stalks. His corn was drilled with one stalk standing every 12 inches as nearly as possible, and with rows three feet apart. Walker Dunson says he believes he can grow 300 bushels of corn per acre if he can keep it from

being blown over or falling down. The boy who wins in 1915 will have to do his best.—J. F. HUDSON.

You cannot claim that this boy had unusual opportunities, for he was ten and a half miles from the nearest railway. Instead of lamenting his unfortunate circumstances as some boys might have done, he just roused up and made the dirt fly. I hardly need tell you that thousands of other boys from Florida to Maine, and, so far as I know, clear on to California, are doing things along the same line; and may God be praised it is not the boys alone. Our young girls (God bless them) are helping the world in the same line.

Here is another clipping, from our Bradentown daily:

MISSISSIPPI GIRL AND BOY MAKE CROP RECORD.

WASHINGTON, March 23.—The best records in the southern corn and tomato clubs for the last year were made by a Mississippi boy, Carl Graves, of Soso, and an Alabama girl, Hester Sartain, of Walker.

Carl raised 202 bushels of corn to the acre at a net cost per bushel of 14½ cents. Hester raised 7037 pounds of tomatoes on one-tenth of an acre, put up 1620 pounds, and made a net profit of \$146.20.

In regard to socialism, it will get along just as fast (or perhaps faster) if we all keep busy and "let up" just a little on finding fault because this great wide world is not in its present stage *altogether* perfect.

Let me touch on the question of wages in closing. There is much complaint, especially from the socialist, that laborers are not paid enough; in fact, there are quite a few extremists who insist that all employees should be paid all they earn—that is, the men who employ workmen should not have any *profit* at all. Suppose you tell a farmer, for instance, that it is not fair nor honest for him to make a profit by employing labor. If I understand it rightly they claim the hired man should have *all* the profit. The owner of the farm should have just enough to feed and clothe himself and no more. When it comes to buying new machinery needed on the farm, I presume the farmer would be allowed enough to purchase the necessary tools. I do not know what they would say in regard to the automobile. Well, a good friend out in California (I do not mean to use any sarcasm by calling him a good friend) recently wrote me that I ought to be sent over to Europe and placed before the biggest cannon, because I owned up that, years ago, I hired juveniles to do easy work, in connection with the bee business, at *three cents an hour*. Let me say here what I did not say before, that those juveniles came around after school and were greatly delighted to

think they could earn a little money by something that was just fun for them; and I happen to know that some of their poor mothers were also greatly delighted to know that their children were employed in something useful, even though they got only three cents an hour. Of course they stopped at any time when they got tired; but they were so delighted with their work that they felt hurt when I told them they had worked long enough. Just now three cents an hour *does* seem small pay; but, my good friend, when I was a schoolboy I rode horse to cultivate corn all day Saturday for 25 cents, which was only 2½ cents an hour, and I was as much delighted with my "two-shilling piece" when night came as you can well imagine. I did not find riding a horse to be drudgery, for the man who employed me was a good kind friend, and I might, perhaps, confess to you that at that time my good father and mother were finding it uphill work to feed and clothe a family of seven children, and the 2½ cents an hour I earned seemed like a Godsend. Now, I leave it to the readers of GLEANINGS to decide whether it in any way hindered my progress because I did thus early in life help to support the family by working all day for 25 cents. As for myself, I can now fervently thank God that conditions were such in my childhood that I had to work thus, even at small pay. Had not my parents been comparatively poor people, I fear I never should have learned to love gardening and chickens all through my life, and clear up into old age. God bless the boys and girls who are at present finding pleasant and profitable occupations in the "corn clubs" and "tomato clubs" referred to in the clippings above.

Even though this article has spun out much longer than I intended, I find I have given little or no advice to the boy who is "crazy" to learn a trade. I presume that during my busy life I have learned to be at least tolerably expert in a dozen different trades or occupations. My first trade, perhaps, was gardening, and my good mother taught me that trade. As soon as I was old enough I commenced visiting expert gardeners or truckers; and later I kept in touch with our Ohio Experiment Station. My father was a carpenter, and he taught me how to care for and use carpenter tools. I never had any other training, except, perhaps, from a brother-in-law who was and is an expert house-builder, although he is now 85 years of age. Of course he does not do very much now at carpentry. For many years I was considered an expert in the line of watch-repairing. I first paid a jeweler

\$25 for two weeks' instruction. After that I worked perhaps a year under instruction, with, say, enough to support myself. Then I started out for myself, as I have told you in former Home papers. There were two fairly good shops in our town when I started; but in three or four years the other two had gone somewhere else. You may be sure I worked early and late. I rarely disappointed a customer. When my health failed from being too much indoors I went back to the gardening of my childhood, and to the chickens, and, later on, bees. My ambition

was to get clear up to the head of the class as fast as possible, no matter *what* I undertook. There are now countless periodicals devoted to every trade and occupation; and through all my life I have availed myself of these helps. With the experience you have had in carpentry with your neighbor as mentioned, I see no reason why you cannot speedily become a good carpenter without any special help from anybody. May God give you faith and skill and energy while you read over once more the two texts I have placed at the head of this article.

HIGH-PRESSURE GARDENING

OUR FLORIDA GARDEN TOWARD THE LAST OF APRIL.

Before we go back to our Ohio home I want to take the good friends who read GLEANINGS through our garden as we take visitors almost every day. I say *we*, because when there are women callers Mrs. Root usually goes along also.

I have told you about the mulberries so much I need not repeat it; but this year we have a *strawberry-bed* also; and when Mrs. Root makes a pie or shortcake now, she adds strawberries, more or less, to the mulberries; and in this way we think both are

roses galore to give neighbors and visitors; and finer roses I do believe than I ever saw before. The collards I have spoken of are now immense, and we are pulling off the lower leaves for the chickens every few days, and it only seems to make them grow better. I spoke of some transplanted onions where I used guano. Well, one row 40 feet long gave 100 onions averaging over $\frac{1}{2}$ lb. each. We put three in a bunch, and they went off quick at a nickel. You can figure up how much an acre would bring at this figure. If we could wait to have them mature they might bring even more money.

Some of them now weigh close to 1 lb. We are still getting \$2.00 per bushel for our Red Triumph potatoes. The yield in our garden is about 1 1-3 bushels per square rod, which would be something over 200 bushels per acre. A socialist friend who seems to object because I advise "the great army of unemployed" to "get busy" growing potatoes in the back yard declares potatoes do not bring \$2.00 per bushel down here in Florida. Per-

The potatoes that grew in six weeks and the brush that brushed the skins off, instead of paring or scraping. They are the Red Triumph, and one potato is shown only partly "peeled."

haps he hasn't seen such potatoes as we grow, say like these above. Mr. Burnett, of the firm of Alderman & Burnett, grocers, said in March, "Mr. Root, it is a pity you cannot bring us 50 bushels of such potatoes, instead of only about one bushel per day." The Cleveland Plain Dealer for April 17 quotes "Florida Hast-

improved. Right in front of the mulberries there are six rose-bushes that cost only 15 or 20 cts. each at Reasoner Brothers' nursery; and although they haven't been out over six or eight weeks we have now a great profusion of roses that would compare with those in the city florists' show-windows. Every morning for weeks past we have had

haps he hasn't seen such potatoes as we grow, say like these above. Mr. Burnett, of the firm of Alderman & Burnett, grocers, said in March, "Mr. Root, it is a pity you cannot bring us 50 bushels of such potatoes, instead of only about one bushel per day." The Cleveland Plain Dealer for April 17 quotes "Florida Hast-

ing potatoes, \$7.50 per barrel." My melons and squashes during the past winter were mostly a failure, owing to the unusual amount of cold and wet weather; but cabbages seem just suited with the conditions. We are growing them mostly for our chickens.

Helianti is growing tremendously since the warm weather. The tubers I brought from Ohio and planted in November have just started; but half a dozen tubers from the Burgess Seed Co., Allegan, Mich., planted in March, came up at once, and are now a yard high. We hope they will give a bigger crop here than they did in Medina.

Later.—To-day is May 3, and I am here at my Medina home; and it occurs to me that I wish to say something more about the Red Triumph potatoes that I have grown with so much enjoyment down in our Florida home. To get \$2 a bushel for the potatoes, of course we have to sort the small or inferior ones. After the sorting they are put on a screen made of one-inch poultry-netting. Those that went through the screen were boiled for the poultry. While they were boiling hot they were taken in a common pail, with the water they were boiled in, to the poultry-yard. With a common fire-shovel they were mashed and chopped up with enough middlings to make a nice dry mash; and the fowls become so fond of them that as soon as they saw me coming with the pail they would run to meet me. Small potatoes, or any potatoes not wanted otherwise, are certainly very profitable for poultry. While feeding our small potatoes we got our best laying of eggs.

Now, I have something more to tell you about small potatoes. Those that did not go through the screen, and were too small to be saved for seed, are used as follows: I made a little basket of wire cloth to hold the potatoes while they were being baked in the oven. The basket kept them from rolling about, and made it easy to get them in and out of the oven. Then they were baked until, when squeezed, they would pop open like an egg. Of course the outside was somewhat charred; but you know charcoal is advertised as a valuable medicine; and I suppose you know, also, that Terry, Wiley, and others have been telling us that not only should wheat be eaten whole as God made it, but that the peeling of the potato contains valuable salts necessary for good health that we cannot well get otherwise. Now, when the roasted potatoes are smoking hot I crush them and drop them into a bowl such as we commonly use for oysters. When the bowl is full, or nearly so, I sprinkle on some salt and pour on some

milk. It seems to me I shall never tire of these roasted potatoes. They agree with my digestion better than anything else; and I feel sure they are a very good substitute for meat, with milk taken with them. Who is there among you who has not had fun in roasting little potatoes outdoors in the fire when you were kids? Perhaps old potatoes would not seem just as luscious; but when you come to eating new potatoes again, just try what I have recommended in the above. It is another short cut "from producer to consumer."*

For the first time during the past winter we have had a strawberry-bed of our own; and those raised beds I have told you about, in the Florida soil, seem to be just the thing for strawberries. We have had strawberries for two or three months—all we could use, grown in our own garden.

Our feterita plants, when we left, had made such a growth during the recent warm weather in Florida that I could stretch some of the leaves up almost as high as my head. One single grain produced from six to twelve stalks; and the plants for green stuff alone, for all domestic animals, including chickens, is worth more than almost any other plant I know of. A plant grown considerably in Florida called "chicken corn" very much resembles it, but the grains are smaller. Another plant called Egyptian wheat (or shallu), although it was only a foot high when I left, so far very much resembles feterita. All three belong to the non-saccharine sorghums.

THE SPINELESS CACTUS.

Last fall (p. 828, Oct. 15) I had quite a little to say about spineless cactus. Some time in December I got half a dozen "slabs" of the Reasoner Brothers. I planted the slabs according to directions, and watched them all winter, anxious to see a bud starting; but we had so much cold wet weather that I did not see any start until about April 1. From that time on they made a most amazing growth. When I left there, one plant had five leaves, each one fully as large as my hand. The growth was so rapid that I could see a difference each morning, and another difference in size when night time came. My good friend Henry Borchert, of Laredo, Texas, also sent me half a dozen slabs of the wild spineless cactus that grows in Mexico. These, although planted later than the others, took a start during the

* Since the above was put in type I find the following from our good friend T. B. Terry, in the *Practical Farmer*: "One of the best authorities in the world tells us that a pound of baked potato is equivalent in total nutritive value to one pound of chicken, or eight eggs, or seven ounces of bread, etc."

middle of April, and were making new leaves or slabs about as rapidly as the others. The Burbank Company claim that the fruit-bearing cactus is a different variety from that which bears just slabs for feeding domestic animals. But the Government bulletin in regard to the spineless cactus seems to insist that they are *all* fruit-bearing, more or less; and now a nurseryman in the northern part of Florida says he has *ten* different kinds, some partly fruit-bearing and some not. The prices are from 60 cents a *leaf* up to \$5 a leaf. Nobody sells cactus *plants*. They sell only the leaves, which they call "slabs." Well, as it seems to devolve on *me* to test these wonderful novelties (?) I sent for a 60-cent slab, and also for one of the fruit-bearing slabs, which cost \$1.75. Now, I did not pay \$1.75 for a *plant*, mind you. I paid the money for only a single leaf, and not a very large leaf at that. Why should anybody pay \$5 for just one *leaf* from a plant, do you ask? Well, this plant (so he says) bears fruit as large as oranges, and more delicious; and the vender of this spineless cactus tells a story about a doctor in Jacksonville who purchased one slab, and in just ten months it had produced 47 *slabs* like the original. The Jacksonville *Times-Union* gives a picture of the plant with its 47 slabs or leaves. Judging from the rapidity with which spineless cactus grows in my Florida garden I can readily believe the thing is possible. Years ago while wandering in a thicket in Osprey—the island where I had my bees—I found a single cactus plant that gave me a little pailful of very nice fruit. I have not seen any of the large fruit; but my friend Borchers, whom I have mentioned, when sending me the cactus slabs sent me also some cakes of a confection made from the juice of the cactus fruit; and at my request he investigated in regard to this confection, and he says it is made from the juice alone of the cactus fruit without any sugar whatever being added. It makes a very nice substitute for a chocolate candy. When you come around to visit me and to go through my Florida garden I will give you a taste of the cactus confection, even if I should not have some *fruit* to treat my friends and visitors.

Speaking about fruit, let me refer again to that tree I have mentioned, the papaya. It gave us five beautiful fruits during the past winter. The largest was 22 inches round and 18 inches long. It looked like a huge watermelon before it turned yellow. It was big enough so that we had all we could use ourselves for several days, besides

giving some to the neighbors and the visitors who happened along about that time. Reference to this tree will be found on page 298, April 1. We saved the seed from this "big melon;" and if you will mention it when writing us I will send you a few to test. Of course the tree will not stand frost. I have grown them here in Ohio by starting the seeds in the greenhouse, almost as high as my head, but they did not bear any fruit.

PAPAYA CARRISSA. THE TREE THAT BEARS "MUSK-MELONS."

One of our visitors, a beekeeper, had a small kodak with him; and although it was a windy day he succeeded in getting the picture above. The boxes standing near the trunk were to support the largest fruit. To prevent abrasion when the wind blew I placed a folded cloth on the scaffolding to support the fruit. See description, page 298, April 1.

Speaking of seeds reminds me that I owe some of you an apology. You will remember what I have said about the Burbank Rainbow corn. We took some of the corn down to Florida and planted a row. To my surprise only about half of the stalks in the row showed the rainbow colors and variegation. Then I remembered that our row of Rainbow corn here in Ohio was but a little way off from our other sweet corn, and the bees had produced cross-fertilization; so the seeds we have been sending to

our friends may not all show the beautiful stripes of so many colors. As we have quite a little left of our own growing, and some more from the good lady in California who sent us several ears by mail, I think I can give all applicants from this time on five grains each instead of three, as mentioned last fall.

Below I give the letter from the kind lady who sent us the Rainbow corn:

Mr. Root:—I am sending you by this mail two

ears of Rainbow (Burbank's) corn that I raised here this year—one yellow and one red ear. I was the only one here who had it (by the way, I got it from John Lewis Childs) in these parts, and all who saw it thought it beautiful. It was over five feet tall, and some had red silk that was lovely. That is the kind that had the red ears; but the seeds I planted were all yellow. I hope this will reach you safely, and that it will grow as well for you as it did for us; and I thank you for telling us how good it is to eat. I hope to try it myself next year. You see the corn-worms had sampled it. They get in all the corn here.

Sunland, Cal., Dec. 25.

MRS. P. BAILEY.

HEALTH NOTES

THE DANA FOOD-CHOPPER, AND A SAMPLE OF THE WAY SOME PEOPLE DO BUSINESS.

Mr. Root:—Some time ago in your department you gave a notice concerning a machine called the Dana food-chopper. I sent to Williams & Co., as directed, and received one by express from them. When I opened it the part used for grinding small grains, etc., was broken. The Williams Co. stated that the chopper they sent me was the only or last one they had in stock. They promised to send the chopper for \$1.25 prepaid. Instead they sent it collect. The express was 60 cents. Since Williams & Co. said the chopper sent me was the last in stock I wrote direct to the Dana Mfg. Co., Cincinnati, to have the broken part replaced. I enclose herewith the answer I received. It appears that for several years this food-chopper has not even been manufactured, and that no parts are available. I was rather disappointed. Now, I haven't written this to complain, but only to show you exactly how the matter went with me. Now, Mr. Root, I'll tell you what we want. We should much like some little tool that we could use to grind grains with for our own use, such as breakfast foods, etc. If you know of any such tool, please give us the name and address of the firm handling it, or the name of the manufacturers. ISAAC D. KREISS.

Escondido, Cal., April 27.

Below is the letter referred to:

Isaac D. Kreiss:—Your favor of the 6th, addressed to The Dana Mfg. Co., and calling for parts for Dana food-chopper, has been forwarded to us inasmuch as we have purchased their entire business. As the manufacture of the Dana food-chopper was discontinued some years ago, and none of the parts are now obtainable, we regret our inability to assist you in the matter.

THE PEERLESS FREEZER COMPANY.

Winchendon, Mass., April 21.

We give the above in order that none of the friends may have a similar experience. We have one of the little food-choppers, and it does the work nicely, and runs easily; but Mrs. Root has just complained that there is one part of the machine that is quite difficult to clean after grinding certain kinds of food. Sears, Roebuck & Co., Chicago, advertise an implement made in several different sizes. The smallest size is only 65 cents; and whatever *they* sell can be returned at their expense if it does not give satisfaction.

Now, here is some good news—at least it

seems so to me—for the good brother who writes us, and everybody else, for that matter. The new cereal, *feterita*, does not need any grinding—in fact, we like it better without grinding. You can grow it in your garden anywhere—yes, even if you have a long severe drouth. When the grains are sufficiently mature you can pound out the grain with very little trouble (for I have recently done that very thing), and cook it without any grinding; and I think you will agree with Mrs. Root, myself, and all the neighbors, that it is ahead of any other cereal, especially if eaten with a little butter and good honey, with a bowl of milk near by. If anybody else has been disappointed in the Dana food-chopper, and will let me know, I will try to make it good.

GOD'S KINGDOM COMING.

We clip the following from that up-to-date periodical the *Union Signal*:

BEER-DRINKING CAUSES ACCIDENTS.

The Western Electric Plant of Chicago forbids its workmen bringing beer upon the grounds. Why?

Because it was noticed that a large number of accidents occurred uniformly after lunch, and in almost every case the victim of the accident had taken beer with his lunch.

TOTAL ABSTINENCE DEMANDED; EIGHTY-EIGHT PER CENT OF THE MANUFACTURERS OF THE UNITED STATES DEMAND TOTAL ABSTINENCE OF THEIR WORKMEN.

Sickness is always more fatal with beer-drinkers, and accidents are usually fatal to them.

About one million railroad men in this country have to be total abstainers from beer and all other intoxicating liquors.

SALOONS IN ARIZONA; THEIR LAST DAY.

To-day is the last day for the saloons, and oh how glad I am! GLEANINGS can well claim its share of the credits for helping to make Arizona dry. Without woman suffrage we could never have accomplished so much good. Mrs. Riggs and I are feeling so good about our statewide prohibition that we are trying to feed more hungry tramps than anybody else in town; but everybody in Bowie is feeding them, I am glad to say. It certainly is a blessing to be in this world to do all the good we can.

T. J. RIGGS.

Bowie, Ariz., Dec. 31.

EDITORIALS

THE first car of bees from Virginia this season arrived May 21. Notwithstanding a large percentage of the colonies were strong, they all arrived in most excellent condition. It is the best shipment, in point of quality and quantity, we ever received. There will be one more car from Texas, and another from Virginia.

Failure of the Tupelo Crop of Honey in Northern Florida

WE have received a letter from A. B. Marchant at Sumatra, Florida, stating that the tupelo that is usually regarded as a dependable crop year in and year out was a complete failure. A heavy storm lasting six days entirely destroyed the bloom.

Bumblebees Wanted

DR. BURTON N. GATES, of the Massachusetts Agricultural College, desires to get a number of specimens of bumblebees that have been caught in the act of entering a hive or that are found about hives. The purpose of this is to enable one of his students to make a study of the behavior of bumblebees in relation to hives. All who have observed bumblebees, or what looks like them, about hives, would be conferring a favor on Dr. Gates if they would send him a specimen carefully packed in cotton, and shipped in a small box, together with a letter giving some information as to where the bumblebee was found—and name and address of the sender.

A Honey Journal

THE former secretary of the National, Mr. Geo. W. Williams, of Redkey, Ind., recognizing that honey has not received its fair share of attention on the part of the consuming public, and with the view of pushing its sale, is about to publish a new

bee paper entitled *The Booster*. Mr. Williams will confine himself to the matter of finding a market for honey; and, as the name of his paper indicates, boosting prices. There is a large and important field here, and we wish our new paper success.

Sixty lbs. Net of Honey in Square Cans

Now that the season is close at hand for putting up extracted honey, we believe the following from one of our correspondents will be very timely:

There has always been a good deal of controversy as to the tare on cans and cases; and if dealers get in the habit of packing 60 lbs. net, this question will be eliminated, and will greatly simplify matters. Another thing, the buying trade now are expecting to have the goods packed in this way; and if it is packed overweight, they do not want to pay for the extra weight.

A Correction

BY mistake we credited the very fine picture appearing on our cover for May 1st to Dr. Bigelow, whereas it was sent us by Alexander B. Stevenson, of Edmonds, B. C. The following characteristic letter from Dr. Bigelow, in which he generously explains that the honor is not his, was our first intimation that we had made a mistake. We beg Mr. Stevenson's pardon for giving the credit to some one else.

Some people achieve honors, and others have them thrust upon them. I am in the second class regarding the photograph that appears upon the front cover of your magazine for May 1st. I believe that is the first front cover that has ever borne my name, although your front cover has carried several of my photographs. But here is the unfortunate situation: That is not my photograph.

EDWARD F. BIGELOW.

Arcadia, Sound Beach, Ct., May 8.

When Mr. Stevenson sent the photograph he wrote that his bees are all hybrids, but that he often works with them without wearing a veil. Hybrids certainly have the

reputation of being very vicious, but some hybrids are as gentle as any pure Italians.

Our cover for this issue is the picture sent us by Dr. Bigelow which is referred to above. Dr. Bigelow writes that neither of the young people had ever handled bees before, and their experience on this occasion was therefore quite a revelation.

A Good Tool for the Apiary

IT is not often that we give an editorial boost to any article advertised in our advertising columns; and when we do, it is because it has extraordinary merit. In this case we refer to the German scythe advertised by the Marugg Co., Tracy City, Tenn. The editor sent and got one of these, and found it so far superior to the old-style regulation style of scythe usually sold on the market, and so much better for mowing around beehives on account of its sharp point, that we believe we are doing our readers real service by mentioning it. It is very light, and seems to have a "swing" about it that makes mowing a real pleasure. The blade is almost as thin as paper, and for that reason it is easy to keep sharp. We have several of the old-style scythes about Rootville; but this German blade is preferred by all, on account of its splendid "execution."

Spreading Brood, Once More

IN this issue, in *Stray Straws*, page 435, Dr. Miller and the editor have a little further discussion on this subject. The sage of Marengo believes that the practice should always be discouraged—at least he does not know of any time when *he* can do it to advantage. On the other hand, in this issue, page 436, Wesley Foster, in his department, says "spreading brood need not be done till the middle of May." But he adds, "It must be done with care." There is an admission on the part of Mr. Foster that it can be practiced to advantage even in Colorado. We in our first editorial, page 345, said there might be times when it would do no harm. Evidently locality has a bearing on the question; and it is evident, too, that the editor has been taking a middle ground between the views and practices of two of our leading beekeepers.

Clover Prospects

THE recent and continuous rains all over the clover belt have started up the clovers everywhere. In some localities these rains have come a little late; in others, in just

the nick of time; in others they will insure a bumper crop—more particularly in northern localities. In all localities, owing to recent cool weather, clover will be from two to three weeks late. The winter-killing in some places, and the hot April drouth in others, gave the clovers a setback. What these recent rains will yet do it is impossible just now to give any accurate forecast; but there will be a crop of clover honey in some localities at least, and some clover honey in nearly all localities.

California Honey Prospects

Referring to this, our manager at Los Angeles writes:

The beekeepers of California have had very bad weather for a month, with the exception of some very helpful rains. Nearly everything else has gone wrong—strong winds, fog, cold, and even light frosts have occurred. Sage is not so far advanced but that, with warm weather, a very good crop of sage honey will be produced. . . . The orange-honey crop will be very light indeed.

Helping the Government to Guess

DATA upon which to base an estimate of the summer's honey crop, and the prices which will result, are being collected by the Bureau of Crop Estimates of the U. S. Department of Agriculture. The second annual spring inquiry was placed in the hands of beekeepers known to the Bureau in April, and should have been mailed May 1.

The queries concern not only the condition of the beekeepers' own apiary, but his estimate of the number of bees in the locality, and their fate during the winter. From the returns on the question as to what caused the death of colonies during the winter, much material ought to be secured of value in preparing for next winter.

That no beekeeper should neglect filling out such questionnaires as these goes without saying. Upon the accuracy of these returns depends the value of the July estimate of probable production, and upon the crop estimate beekeepers will rely to some extent for their marketing plans. By co-operating to his best ability the beekeeper can easiest serve his own interest.

Poisoning Bees by the Use of Arsenates; Another Angle to the Discussion

IN this issue, page 436, Wesley Foster refers to our editorial on page 390, wherein Professor Woodworth, Horticultural Commissioner at Pejario Valley, California, gave it as his opinion that the bees are not poisoned by spraying-liquids. It will be remembered that a colony of bees was plac-

ed in the center of one of these big orchards in California. The trees in the immediate vicinity of the hive were fairly doused with the arsenide of zinc. Mr. Foster does not think the evidence is conclusive that the bees in that one colony gathered any of the poison, as the profusion of bloom would be so immense that the bees that were flying could go far enough away to get nectar from blossoms not sprayed.

He also says that as soon as the bees on the western slope of Colorado were removed from the districts where the spraying liquids fall on the cover crops under the trees the losses immediately ceased. This fact is somewhat significant.

We understand that the national Government is working on this proposition to determine whether the bees are killed by the spraying-liquids used on fruit-trees. We shall await with interest that report.

California vs. Canada; Why Queens that Lay Every Month in the Year are Superseded Quicker than those in the North that have Six Months of Rest

On page 440 Mr. Byer is surprised that the majority of Mr. Chadwick's colonies containing two-year-old queens degenerated into laying workers. Perhaps we can explain the situation. Mr. Chadwick is a mail-carrier for Uncle Sam. His bee and garden work he has to do between times. His outyard is located some four or five miles from the home yard. As he does most of the work himself, or did up to this season, it is easy to see something might happen among his bees.

Mr. Byer probably does not take into consideration the difference between his own locality and that of southern California. Mr. Chadwick's bees can fly nearly every month in the year; and the result is, his queens will be laying every month in the year; and two-year-old queens in California are almost the equivalent of four-year-old queens in Canada, where the seasons are only half as long. A queen that lays only four or five months in the year, or six or seven months at the most, can recuperate, where a queen that is laying almost every month in the year has no such opportunity.

In our migratory beekeeping in the Southland we have discovered that a queen that is continually on the job will play out much sooner than those that have a long winter's sleep or rest. These facts will explain why a two-year-old queen may be followed in California by a laying worker.

Things happen pretty rapidly in California. It is possible, however, that Mr. Chadwick has a sprinkling of Cyprian or Holy Land bees. These bees will quickly degenerate into laying workers.

The Distribution of the Bee and Fruit Industries in the United States; a Remarkable Coincidence

GREEN'S *Fruit-grower* is sending out a map furnished by the Chamber of Commerce of the United States, showing the relative amount of fruit grown in each state. The quantity produced in each state is shown by circles of various sizes. These circles are then subdivided by triangular sections in shape like pieces of pie big and little. Apple-growing (as shown by the big "pieces of pie") represents on the average about half of all the fruit if we leave out California and Florida. Strawberries, grapes, plums, and peaches each make a "piece of pie," to carry out the figure. In Florida, as would naturally be expected, oranges represent 90 per cent of all the fruit grown.

But the showing of this map that is most interesting to beekeepers is the fact that, where fruit-growing is shown by a large circle, beekeeping is also well represented. In other words, the states having the largest circles are also big bee and honey states as our records show. For example, California has the largest circle, and, as is well known, beekeeping is an important industry there. Then come New York, Michigan, Pennsylvania, Missouri, Ohio, Iowa, and Washington. In all the states mentioned, beekeeping as an industry is important in about the order given; and while, of course, it does not begin to compare in volume and size with the fruit-growing industry, a careful comparison of the map shows that beekeeping and fruit-growing go hand in hand. While this does not prove that one is directly dependent on the other, it does show that conditions that are favorable for the one industry are also favorable for the other. The great Creator had a *purpose* when he made it possible for the two to thrive side by side. In that "purpose" there is implied a recognition of the dependence of the fruit-growing industry on the bees.

Practically the only exception that we find between the relation of beekeeping to the fruit business is in Texas. Texas is probably second in importance in the production of honey in the United States, and yet it is almost at the bottom of the list in the production of fruit. This disparity is

explained by the fact that Texas produces large amounts of honey from plants and trees grown in the semi-arid districts. When water is once let on to these lands, they will at once grow fruit. Then Texas will come forward as one of the great fruit-growing states of the Union.

Serious Results from Beestings; what Precautions to Take

MR. CHADWICK, in this issue, page 437, in his department, tells of an experience that "came near being a tragedy" in his home. His wife, always more or less susceptible to the effects of beesting poison, was, on the occasion mentioned, stung by a bee just back of the ear (a bad place by the way). As she had been stung several times prior to this, without any serious results, she had not taken pains to keep away from the bees. But this time the sting had more than its old-time effects. A doctor was called, and soon she was out of danger. She was left in a weakened condition, however, and remained in bed for the rest of the day. This was very wise, as absolute quiet—at least no bodily exertion—should follow after a case of severe stinging.

We once had a case where a young man was stung a great many times. He became dizzy, and broke out in blotches. He was given a heart stimulant, and apparently revived. He took a tepid bath, and felt so much better that he said he did not see why he could not go back to work. After he had got his blood warmed up he had a fainting-spell, became unconscious, and his heart action had all but stopped. Fortunately we were at hand with an automobile, and rushed him up to the doctor at the limit of its speed. The great volumes of fresh air partly revived him, but it was evident he was in a serious condition. The doctor gave him a heart stimulant, and directed us to take him to a quiet place where he could get fresh air. We put a small electric fan in front of his face, and in a short time he was revived enough so he could talk to his friends.

The doctor afterward, in speaking of the incident, made this statement—that after one has been stung, or has received a general shock like this on the heart, the patient should be quiet for several hours. It was very important also that he do no work requiring bodily exertion for *several days*. After about two weeks we took this man to a specialist in Cleveland, and he reported he was in as good condition as ever. But it was evident that he had received a temporary shock.

Two or three times when we have published accounts of severe stings, some of our subscribers have come back at us that we should suppress the facts. We do not believe in anything of the kind. Beekeepers and others should be warned. Fortunately there is not one in a hundred thousand who is seriously affected by stings. Indeed, we may say we hear of hardly one in a million. All the newspapers in the country put together do not report one case of severe stinging in a year, in a population of about a hundred million. This shows that the average person has little to fear from one sting.

Our junior editor, Mr. H. H. Root, was at one time very susceptible to the effects of a single sting. He, too, would have fainting-spells and attacks of dizziness. On several occasions we were greatly alarmed, but he always managed to pull through. He had an ambition to follow in the footsteps of his father and brother. The last mentioned suggested the scheme of gradual immunization. This was accomplished as follows:

A bee was picked off a comb, and pressed gently against his hand. Just the moment that the sting pricked the skin, and before any considerable amount of poison could get into the wound, the bee and the sting were quickly removed. This was repeated a week afterward. At the end of four or five weeks there was an uncomfortable itching sensation. The hypodermic injections were then discontinued for several months and then resumed again. Afterward the patient got so he could take two sting pricks a week, then three, and finally it was discovered he could take the full effects of a sting without any inconvenience. It was not long before he went among the bees, and handled them as did his older brother. On one occasion when we went out together with a load of bees one hive was spilled overboard, releasing a lot of bees. The two of us each got something like thirty stings; and, remarkable to relate, the younger brother experienced no more harm than the older brother. He is to-day as immune as any of us.

To provide against a possible recurrence we suggest that Mr. Chadwick try out the same scheme on his wife. He should be very careful, however, to see that the first sting prick is *only* a prick, and that all subsequent sting pricks for a considerable time should merely pierce the skin. Suitable tweezers should be provided so that the poison-sac will never be squeezed in removing the sting.

C. C. Miller

STRAY STRAWS

Marengo, Ill.

H. P. KIRBY, when bee-hunting, takes vinegar to dilute honey. p. 409. Why vinegar rather than water?

W. C. MOLLETT, in comparing Italians with blacks, p. 413, you omitted one marked trait of superiority in Italians. A weak colony of Italians will clean out the bee-moth where a weak colony of blacks will give up and die.

G. M. DOOLITTLE, p. 398, testifies "from many experiments and much careful observation," that queenless bees select for queen-rearing larvae about 36 hours old. Thanks, friend Doolittle, for your expert testimony against the libel that in their haste for a new sovereign they choose larvae too old to make a good queen.

I WONDER how many beekeepers take care that no young queen be reared except from the best stock. And then, of those who are thus painstaking, I wonder how many pay any attention to the drones. Yet we are told that the drone is just as important as the queen. It isn't such a very hard matter to encourage drones in a few of the best colonies, suppressing them in all others.

A SEVERE slump has taken place in the market value of Chicago's 7152 saloon licenses. A year ago they brought \$2500 to \$2800. This year, 89 licenses came into the possession of Judge Landis through the failure of The Tosetti Brewing Co., and he could get no bid higher than \$1200 for a license. It would be hard to say just how much this is due to the fact that a great dry campaign is to be waged in Chicago, with Billy Sunday in the thick of it. [What is taking place in Chicago is taking place in many other cities and towns in the United States. The saloon crowd is panic-stricken, and on the run.—ED.]

THAT vigorous editorial protest against spreading brood, p. 345, would do good service if it were printed each spring, for each spring a fresh lot of beginners come into action, and one of the first notions a beginner gets into his noddle is that a sure way to hurry up brood-rearing is to shove an empty comb between two combs of brood. I think, however, that you are making a pretty liberal concession, Mr. Editor, when you say that under some circumstances "it may do some good." I don't dare to say that my experience should be a guide for every one, but I will say that in my locality and with my bees brood can be spread in

spring always and only at a loss. With plenty of honey in the hive, my bees always have all the brood they can cover, as soon as they get fairly started at brood-rearing; and pray tell me how spreading can make them cover more. Doesn't any good queen anywhere have all the brood in spring her bees can cover? [We do not know but that we agree with you; but if you will look at the editorial again we think you will see that the only time when spreading brood might do no harm, or might be an advantage in the spring, was during a spell of continuously hot weather. If it did not turn cold shortly after, it might do no harm. Generally speaking, the beginner should let the spreading of brood alone. Bees may not know much, but they know a whole lot more than their owner who knows more than he ought to know.—ED.]

POLLEN is generally understood to be found in honey, at least a few grains here and there. It is doubtful, however, whether all beekeepers understand to what extent this is the case. The English pollen-expert, Mr. G. Hayes, says, *British Bee Journal*, 117, "You will remember that the pollen-grains are distributed all through the honey, and you can scarcely put in a needle-point without taking out pollen-grains." [The presence or absence of pollen in any sample of suspected honey goes a long way toward determining whether the honey is pure or impure. For example, invert sugar has many of the characteristics of pure honey. At one time certain unscrupulous venders thought they could adulterate honey with invert sugar, and escape detection; but they found out their mistake, for the chemists found that their adulterated samples contained too small an amount of nitrogenous matter—pollen.]

The fact that there is always some pollen in honey explains why bees will breed up on it better than they will on sugar syrup or any other artificial product. This also explains why colonies in the spring that have a good supply of *natural* stores will be stronger in the spring than colonies having only sugar stores. The former will breed up on honey when they could not do so on sugar; hence the relative difference in strength in the spring between the two sets of colonies. But that does not argue that sugar syrup is not better as a pure wintering food. If with the sugar stores there were combs of natural pollen the difference might not be so marked.—ED.]

BEEKEEPING AMONG THE ROCKIES

Wesley Foster, Boulder, Colorado.

HONEY PROSPECTS.

Bees came through the winter with not an excessive loss in any districts of the Rocky Mountain region. The cold backward spring was not very conducive to building up early, and some weak colonies died during the long-continued cold weather in March. However, during April breeding was done, and the weak colonies with good queens certainly made a good report of themselves.

Bees are not swarming in May this year as was the case last year. Early in May the Rocky Mountain region was visited by freezing weather that ruined a large proportion of the fruit prospects in western Colorado and elsewhere. At the time of this freeze the alfalfa was up nearly one foot, and much of the fruit was in full bloom; bees were preparing to swarm, and a number of colonies had swarmed in Delta County. The freeze was a very serious thing for the fruit men, and put back the honey season several weeks, no doubt.

There has been such a generous amount of rainfall this spring that it is doubtful whether the shortage of irrigation water will be felt. The reservoirs are now fuller than it was hoped they could be, so that there should be water enough in most districts for the late irrigation.

The precipitation so far this year is $2\frac{1}{2}$ inches above normal; and if it keeps on raining we shall have plenty of moisture.

Sweet clover is thicker this year than last; and while it was frozen down pretty badly it will recover.

DRIFTING BEES.

Bees cut up some queer capers when a large number of colonies are placed in one location. Recently we were preparing 800 colonies for shipment; and to facilitate loading, about four hundred were placed close to the switch. Entrances were contracted prior to moving, and the hives were faced east and south, so that as little confusion would result as possible.

When the apiary was inspected the opening of the hives caused more drifting. Some drifting had been going on all the time until a number of hives were simply running over with bees while others had hardly enough to care for their brood. Almost wholesale distribution of the bees had to be done, and many weak colonies were placed on the stands of the strong ones. The bees were necessarily very cross from this mix-

ing-up; but the bees were finally pretty well distributed.

In order to prevent drifting, do not place colonies too close together; and avoid long straight rows all faced the same way. Do not release the bees so they rush out of the hives all at once (as they do when overheated). After moving an apiary it is best not to examine the hives if any drifting is going on, as the opening seems to aggravate the trouble more.

BUILDING UP COLONIES FOR THE FLOW.

It is certainly surprising how rapidly a very weak colony will build up if it has a young vigorous queen, plenty of honey, warm weather, and abundant pollen.

Proportionately a weak colony will build up faster than an average or a strong colony. There is such a thing as having a colony too strong early in the season. If you have, or can get, extra queens at the right time, increase can be made from the strong colonies without impairing the honey crop. It is all a matter of understanding how to take advantage of the season and its eccentricities.

In western Colorado I saw swarming the latter part of April. On a Thursday bees were swarming. Friday it was freezing, and Saturday it snowed. Such changes in the weather are hard on bees, especially swarms. Old colonies can protect their brood in pretty cold weather, as they are pretty populous at this time of the year.

In all that a beekeeper does he should work cautiously in the spring. Spreading brood need not be done till the middle of May, and then it must be done with care. Bees will spread their brood if they have abundant pollen and fresh nectar from fruit bloom and dandelions.

Most of our beekeepers are now busy equalizing stores, inspecting their apiaries, and getting things in shape for the honey-flow that is not due ordinarily till June 15 to July 1. Our season is now late, and July 1 will come before sweet clover blooms.

IS THIS TRUE SCIENTIFIC METHOD?

There has been so much said about spray poisoning that it may be out of place to say more; but the opinion of Professor Woodworth, that bees are not poisoned by spraying with arsenite of zinc, and that bees are not poisoned by arsenate of lead, is worth an answer.

Professor Woodworth should conduct his experiment with a hundred colonies instead of one. It should also be remembered that

Continued on page 439.

BEEKEEPING IN CALIFORNIA

P. C. Chadwick, Redlands, Cal.

We welcome the "Dixie Bee," and would suggest that it be the queen of the department pages.

The future at this date is all guesswork. The button-sage bloom will be increased but little if any.

Whether the rain will cause a heavier flow of nectar from the limited amount of bloom cannot be foretold. There will not be more than 50 per cent of a normal bloom, which will be sufficient if it yields well. The white sage never looked better, and the same is true of the wild alfalfa. I am expecting a slow flow from all these sources, and a prolonged season, but what the net results will be I cannot say.

Beautiful sunny southern California! Yes! No! Well, I guess not so you could notice it during the past three weeks (May 8). It is doubtful if worse weather has ever visited this section than that we have just had. On April 13 a storm struck here that did not entirely abate until May 8. Cold, hail, snow, heavy rain, and very little sunshine has been the program. During this period the temperature reached the lowest point of any day in May for 34 years. For three hours on April 30 my Tremont apiary was in the midst of a heavy snowstorm. Bees were driven out of the supers, and forced to cluster for protection. In many localities not in the orange districts feeding became necessary, and the entire bee business came to a sudden standstill. The best part of the orange season passed under these conditions, with the finest chance for a record-breaking orange-honey crop at hand. More than 5½ inches of rain fell in this locality.

The past three weeks has afforded an opportunity to study the effect of bad-weather conditions on field bees, and I have improved the time with experiments. I am better satisfied now than ever before that bees will not stand the exposure many think they will. During the time of these experiments the temperature ranged between 40 and 50 degrees, and showers were frequent, with but very little intervening sunshine; but we were not without sunshine to an extent that thousands of bees were enticed to the field, only to be the victims of cold rain. I proved to my entire satisfaction that nine out of ten bees will

die if they are wet during the day and not able to dry or warm up before the next day. In one experiment I watched the actions of a small bunch which had fallen to the ground when a swarm had been shaken into a basket during a shower. This bunch contained perhaps a hundred bees. The day they were rained upon afforded them no opportunity to return to the hive; but on the other hand they were wet several times during the day and night. At the end of the second day the entire outer layer of bees had died. They were removed from the cluster, after which more rain fell, the second day more had died. Out of the entire number not one bee was alive at the end of the third day.

Some were carried in a basket and set indoors. At the end of the third day most of those had died. I do not believe that the mortality rate in bees was ever heavier than during the past three weeks. I had one colony of bees which were working in a shallow super, drawing combs, that were not able to muster force sufficient to return to the super to-day (May 11), to continue comb-building, although the day has been a hot one. Fifteen dead bees were counted on the sidewalk within a distance of two blocks. Wetting in cold weather is fatal to bee life.

A bee-sting has always been looked upon by me as a painful little joke, and I have wondered many times at some of the stories written of bee-stings causing the death of persons. That day is over with me. On May 4 the effects of a sting came near ending in a tragedy, and I wish here to warn those who are poisoned severely by their stings to avoid them if possible. I had just come home in dinner on the date mentioned, and my wife came to the back steps to greet me. Before she was aware of any danger a bee (without warning) stung her on the head just above and a little back of the ear. The suffering was intense from the very first. I took her into the house, removed the sting, and applied some ammonia, but to no avail, for she began to turn white, and coughed violently. This was followed by vomiting, loss of sight, and turning purple. Meantime I saw danger, and called a physician.

In thirty minutes from the time she was stung the doctor was present. The first move he made was to test the pulse. Ther-

Grace Allen

THE DIXIE BEE

Nashville, Tenn.

That was an interesting article on page 242, March 15, "The Alexander Method Adjusted to a Clover Locality." I think that was just what we had been looking for—some adaptation of this famously successful method to localities dependent on clover. We are likely to try out a plan like this ourselves.

* * *

One evening, about the 27th or 28th of April, the moonlight that flooded our hives and yard seemed deliciously fragrant. "Can honeysuckle be in bloom somewhere around?" we asked, but doubted. But when a neighbor reported next day that our bees threatened to carry her blossoming locust-tree quite away, we understood and rejoiced. That was probably one of the first locusts around here to come out, but now they are in full bloom.

* * *

The reputed effect of patent-medicine advertisements is to make the reader immediately certain that he has some if not all of the symptoms described. And looking at those pictures of foul brood, and reading descriptions of it, makes some of us who are fortunately unfamiliar with it shiver with the wonder if we haven't some combs that look just that way. Is it like measles, bound to come, and the sooner the better? Less difficult, perhaps, while you're small.

* * *

It was such a dry April! Day after day of beautiful warm sunshine, but no rain, no April showers. Our fond hopes of clover were beginning to wither. But then we read in April 15th GLEANINGS, pages 326-7, Mr. Adam Leister's favorable comment on "the very light rainfall for the spring months," with the assurance that "to make up for this we are sure to get an abundance later." And now, May 6, we have just had a splendid life-saving sort of rain, and our hopes are reviving.

* * *

Our neighbors are very kindly disposed toward our bees; but one thing that has proved troublesome until this year was our bees' fondness for the water at one neighbor's pump and hydrant. So this year we followed the suggestion we had seen in the A B C, and put water out for them very early in the spring, when they first began to fly. We salted it slightly, put it in a common Mason jar, laid tiny bits of thin strips of wood across the mouth after filling

the jar, inverted a shallow pie-tin over the top, and then, holding the tin with one hand, tipped the whole combination upside down. Later, this one jar proving insufficient, we added another. We fill them every morning when we water the chickens. Watering bees is no more trouble than watering chickens. And it is an interesting sight to see these crude and decidedly amateurish-looking water-arrangements crowded with bees all day. They measure well up to the traditional popularity of watering-resorts. The water-plant arrangement mentioned on page 246, March 15, promises more of artistic effect, and probably we shall try out something along that line next year. Meantime our bees and our neighbors are at peace, and so, therefore, are we.

* * *

ITEMS FOR BEGINNERS.

Please, all you brother and sister beginners, be sure to use full sheets of foundation and wire it. We didn't, at first, and now we are breaking our hearts over a lot of drone comb. We just hadn't paid much attention to the combs before—combs were combs; but now we are putting those poor ones into the supers to let the brood hatch out, then the bees may store what honey in them they can and will, and then goodbye to those combs. And we shall have as perfect ones as we can get in the future.

Even if you have only two or three colonies, start right in keeping a record of them. It is a wonderfully good habit, and will be more than worth while. You need not condense your comments as much as the big beekeepers do, either. You have more time than they, and far less experience. Better put down everything you observe in the condition of each hive whenever you examine it, whether you understand that condition or not. Record how much brood and stores each one has, and what you did about it; raised a frame of brood, perhaps, to give the queen more room, and inserted a sheet of foundation in its place. (Though of course, you would not do that except to a strong colony, after settled warm weather had come.)

Of course you are dreadfully worried about robbers. Every time you go through a hive, and then see an exciting number of bees in a vibrating sort of cloud around the entrance, you are convinced that that stand is being robbed. Perhaps it is. Probably it is not, especially if there is a honey-flow on. Since our first direful experience, when we took a quart or two of dead bees from

in front of two hives, we have been as nervous as kittens. Another slight case, but immediately recognized, occurred the first time we went into our bees this spring. But many times since then the signs, superficially observed, have seemed to cry wolf, when there was no wolf. Just a day or two ago, after looking into half a dozen hives, I was loafing around, watching the bees fly (and is there anything more fascinating?), when there—surely that hive was being attacked! And that one! And still another! But a second and more deliberate look showed that the bees were merely playing in the sunshine. I had finished work about one o'clock, and that approaches an hour especially popular for the gambols of the young bees. Drones were among them that day too; and the sound of the happy little things was quite different from the voice of robbing bees.

Later.—Noon, May 8. A child with a

white-clover chain about her neck! It must have come!

* * *

Mounting on wings of undaunted desire

Straight through the heart of June's opal and blue,
Bees, how you flash! How you strike out and soar!
Are you daring your dreams to come true?

Daring your dreams! As a flame dares the fire!

They'll come true!

They'll come true!

June in the heart of you, June in the wings!

June in the part of your spirit that sings!

Bees, are you spirit? Or breathless desire,

Or the rapture that dares to aspire!

Daring to dream and then daring to do!

They'll come true—

Those brave dreams—

They'll come true!

If all of us had the persistence and the apparently eager zest for effort that the bees show, most of us would come nearer the achievement of our own fair dreams.

BEEKEEPING AMONG THE ROCKIES—Continued from page 436

bees will fly a considerable distance and may not work in the orchards in which they are placed. I believe it has been demonstrated that bees prefer to fly some distance rather than gather nectar close to their hive.

The conditions mentioned by Professor Woodworth were ideal for that colony *not* to be poisoned to any appreciable extent. There was such a profusion of bloom that the bees probably had not one chance in ten of gathering nectar from sprayed bloom. If arsenite of zinc is repulsive to bees it is welcome as a spray liquid, for it is a matter of quite common knowledge that arsenate of lead attracts them. Bees are quite often seen around the spray-tanks. It is possible the bees attempt to utilize the arsenate of lead as a substitute for pollen, or they may be in search of moisture when hovering about the spray-tanks.

The presence of other honey-plants upon which bees may work is an important factor. If alfalfa, sweet clover, alsike, or other

clovers were in bloom when spraying is generally done in Colorado, I doubt whether any losses of bees would ever be noticed. All the loss seems to come when the orchards contain the only bloom available.

The only reports I have received of bees dying from poisoning during the past four years have been from commercial-fruit districts, except one or two minor ones. Bees were reported killed by poisoned syrup sprayed upon sugar-beet leaves to kill grasshoppers. I saw bees dying, apparently from the effects of poisoning secured from a pail that had contained sheep-dip liquid. Quite a number of colonies were weakened last year near Denver by the supposed poisonous effect of smelter or city smoke.

The most significant point in this matter is that thousands of colonies of bees have been moved from the orchard districts with success. The trouble ceases when the bees are moved, or very soon thereafter.

BEEKEEPING IN CALIFORNIA—Continued from page 437

he quickly prepared a hypodermic injection to restore the action of the heart, which had by this time become very low. In a few minutes the injection had taken effect, and the danger had passed; but she remained in bed the rest of the day, and for the next three hours I wrung cloths out of hot soda water and applied them to her neck. The weakness from this experience remained with her for a week. Strange to say, the swelling was of little consequence; in fact,

it amounted to less than from any sting she has ever had. The physician said that the sting of a bee is as poisonous to her flesh as the bite of a poisonous snake would be to many persons. I certainly do not care ever to see any one suffer to such an extent from a sting again. Mrs. Chadwick was almost heartbroken to think that she must give up helping me with the bees, for recent stings, previous to this one, had led her to think she was becoming immune to their poison.

NOTES FROM CANADA

J. L. Byer, Markham, Ontario

An early spring here in Ontario, and all kinds of vegetation, including the clovers, are looking well. The latter part of April was unusually warm for this latitude, and everything came on with a rush.

In fact, there was such a rapid growth that we feared late frosts might seriously affect the tender growth. But during the last ten days we have had cool wet weather, and the growth has been held back somewhat. All things considered, this is for the best.

For the information of Dr. Bruennech, page 245, let me say that I am not "pretending" when the statement is made and can be substantiated that in our Cashel apiary we had a Carniolan queen that lived till her seventh year. She was not at all profitable during the last two years of her life, but was kept as a curiosity to see how long she would live. Her five first years had been so profitable to us that we did not begrudge giving her a full lease of life, even though she was not so capable during the next two. But, as Dr. Bruennech intimates, four years is the limit of most queens according to my observations—in fact, very few from the matter of economy should be kept that long.

Bees clustering out in April is an unusual experience for us. While little of this was noticed at the apiaries here in York County, the fronts of the winter cases at the north yard were covered with bees in the evenings during the warm spell in April when bees were on soft maple. As a result, many colonies had to be supered at that early date, and the queens at once started laying in the upper stories. With normal spring weather from now on, the majority of the colonies in this yard will have to be relieved of old honey to allow the queens room. While the general verdict is that aster honey granulates rapidly, in this case there is none of the granulation in evidence at this late date, and I never knew bees to winter outside on such a small amount of stores.

G. M. Doolittle is one of our closest observers; and this being the case I read with much wonder his statement on page 312, April 15, that he had never heard a queen "pipe" except on a comb. The matter is beyond my comprehension when I remember that Mr. Doolittle has been handling

queen-bees nearly all his lifetime. Time and time again I have brought a package of queens home and placed it on a sideboard, and the children would soon be listening with interest to the challenging notes from one queen to another. More than that, I have heard them quacking in the box in the postoffice when a number were tied together, and it has been a common thing to have them thus exercising in my pocket on the way home from the postoffice.

P. C. Chadwick, page 353, says that, among the number of his two-year-old queens that have played out, the majority of such colonies have fertile workers. Another mystery to me, surely! Is it in the strain of bees, or what? While I do not for a moment claim that there is no such thing as fertile workers, yet in our yards their occurrence is rare indeed. And as we do not practice systematic requeening, we have some queens play out too—in fact, far too large a percentage to please me. But in at least 99 cases out of 100, either an old played-out clipped queen will be present, or else a virgin that has been reared too early in spring to get mated. To be perfectly honest in this matter, I cannot say that I am sure of ever having had a genuine case of laying workers. The few times we imagined such was the case, we were not sure but that a small virgin might have been present.

Recently I received from Mr. Samms, of Mars Hill, N. C., a pail of "chunk" honey of delicious quality and appearance. The source of this honey—basswood—rather surprised me, as we do not generally find basswood honey so far south. I frankly acknowledge that the quality is equal to our own basswood honey, both in color and flavor. By the way, the term "chunk" honey does not appeal to me at all, and I wonder that our southern friends—more particularly those of Texas, where this style of putting honey on the market originated, if I am correct—do not get some more attractive name for honey marketed in this way. From North Carolina we have had samples of three beautiful lots of honey—basswood, locust, and sourwood; and for my own part, at least, the term "southern honey" has a much better sound to me than it did a few years ago. [A large number of the southern producers now favor the better name, "bulk comb" honey.—ED.]

CONVERSATIONS WITH DOOLITTLE

At Borodino, New York.

LONG WINTER CONFINEMENT OF BEES.

"Will Mr. Doolittle tell us how long a confinement bees can stand and come out in fairly good shape? My bees were confined to the hive from Nov. 10 to April 15 the past winter, a period of over five months, and as a result I have lost quite heavily. Besides, I have now on hand several colonies which are too weak, through spring dwindling, to be of much use before the buckwheat flow. Did you ever know of anybody having bees confined that long?"

This certainly was a long confinement for the bees. But in going over my old diaries I find that this is not the longest period, for during the winter of 1903 my bees had no flight from October 30, 1903, till April 5, 1904, or during a period of five months and six days. Some of the colonies appeared not to have suffered materially by this long confinement, at the time; but afterward they gave proof that this long holding of their excrement told on their vitality, while none of the colonies wintered on their summer stands were what could be called perfect colonies by the 20th of May. Nearly all had dwindled more or less, while several had died.

After April 5 we had more cold, and snowstorm after snowstorm, followed by clouds and cold winds, so that it was impossible to remove the bees before May 2. This had much to do with the poor results with those wintered on their summer stands, but I do not think it possible that bees can be confined for more than five months on the summer stands, and come out in perfect condition for the summer's work.

On May 2, 1904, the bees were removed from the cellars, those at the out-apiary on the forenoon of that day, and those at home in the afternoon. This gave a confinement for these cellar-wintered bees of three days more than half a year, and, if my memory serves me rightly, a longer period than any that has been recorded up to the present time, which is something worthy of being jotted down.

How did they come out? There were three colonies at the out-apiary short of stores, since they had only about eight pounds each at the start. I expected to feed these from the reserved combs of honey stacked there, but the winter swooped down before I got to it, and I thought I would risk them rather than open the hives to set

in combs of honey with the mercury hovering near the zero mark. These three starved, and I find this written in that old diary: "I am ashamed to record the starving of these three colonies, for away back in the eighties I lost a good colony in April from starvation, and at that time declared that should be the only one whose dead bees should accuse me of such wickedness. It is wicked to allow anything which has served me so faithfully to starve." Three other colonies had diarrhea, and died while the rest came out in as good shape as in average years. Those in the special repository at home came out fairly well; but a few of them showed spring dwindling slightly.

When the farmer and I entered the cellar to carry out the bees, the first colony we took showed no signs of life. The hive was set on the cellar bottom, and knocked upon—no response. It was set aside as "dead." As we came to the starved ones they were set on top of this one, and these dead colonies left in the cellar till all were out. The hives had been set in the back part of the cellar, with the entrances toward the wall, in which there is no window. This prevents any light from shining directly in at the entrance. When all were out, the farmer asked me if he should carry out the dead ones and pile them up with the hives of reserved combs. I admitted that he might. All went well till he came to the last one (or what was the first one we took in), when I heard an outcry. I found the bees just fairly boiling out of the hive he was bringing from the cellar. The wet cloth used in removing was hastily thrown over the hive, and it was carried to its stand. And, strange to say, that "dead" colony was the nearest to a perfectly wintered colony I ever had seen or ever have seen since. No dead bees were on the bottom-board, no spotting of things on their first flight, and no dwindling afterward, and that after a confinement of three days over half a year. This colony had not consumed half of the eight pounds of honey the light ones had eaten and died. I had been told in the past of colonies which were so nearly dormant as to be apparently lifeless while in winter quarters; but to see such a thing with my own eyes was something of a "surprise party" to me.

I have pondered over this very much since, and experimented, looking toward bringing the whole apiary up to such a standard of wintering; but as yet, little advancement has been made.

GENERAL CORRESPONDENCE

BUYING AND KEEPING BEES IN LOUISIANA

BY G. FRANK PEASE

Having made up my mind to buy more bees I finally planned an automobile trip south through Indiana, Kentucky, Tennessee, and Alabama for that purpose.

On Dec. 12, 1912, my wife and I started from Battle Creek, Mich. Our load consisted of a camping outfit containing a table, three chairs, stove, box of cooking utensils, grub-box, box of tools, trunk, bedding, tent, canvas cover for auto, two guns, thirty traps, fishing-tackle, four extra tires, and some other necessities. When loaded, the outfit weighed two tons.

would send the dog clear over against us, and brakes squealing so that if something had broken we would have been dashed many feet over steep embankments.

We had to change tires thirty-four times between Michigan and Birmingham, Ala. Sixty-inch ruts caused much trouble, for our auto was only fifty-six inches between wheels. A number of times we had to go many miles out of our way (on account of washed-out bridges), leading us often into deep chuck-holes that had to be made with a dash.

A corner of one yard in the spring soon after transferring.

We started on rough frozen ground, and wound up in the clay mud of the southern rainy season. Many times we were in mud above all four hubs, and had to pry up the auto and lay rails to run out on. We crossed nearly one hundred streams. One stream was sixty rods wide, and in two places the water reached the floor of the auto. It was rain, rain, rain, and mud, mud, mud, for days and days.

We coasted a mile in a number of places, and four miles in one place with the engine cut off and brakes set. We had to twist and wind down some hills with bumps that

'Most beekeepers (except the few who were up to date) kept their bees in tall gums or hollow logs cut off and set up on rocks. But few bees could be bought at a place, and it would have been hard to buy more than one hundred colonies in any one locality; and it would have been necessary to draw them over rough roads from ten to twenty miles to get them together in hives that would hardly hold together.

One man having a number of colonies claimed he could take twelve worker bees and one drone and make a good swarm in three weeks; and yet he would sell no colo-

G. Frank Pease's work-tent, 26 x 44 feet, in which all the supplies were put up.

nies, although making them was so easy. Many people thought king bees rule the swarms, and some thought if one could catch a king bee all the bees would follow. Some thought there ought to be good honey-flows from oak and pine trees, and many other trees and plants.

In answering advertisements I came in touch, through J. B. Marshall, of Big Bend, La., with 324 stands near Shreveport, La., which I purchased in March, 1913, and for which I began the task of preparing new hives. In this task I was limited in time,

as the honey season was just coming on, and I also had to wait until April for my new supplies to come. All I could do was to make new hive bodies, fill them with wired frames of foundation, set them on top of the old hives, and let the bees build combs and start brood in them. But few were transferred until the next season. As the season was poor, few bees swarmed. The honey was only forty pounds per colony, spring count, and an increase to 356 colonies.

My real work commenced in January, 1914, on my return to the South. Although I had left from thirty to sixty pounds of honey stores per colony the fall before, I found that they were in a starving condition, due to a warm winter and much brood-rearing. Since this starving condition made transferring easy, I began transferring, and fed as fast as I changed.

Nearly half the colonies had brood in both the old and new hives. Setting the new combs, with what little honey and brood was in them, in a new hive-body, and cutting and transferring the brood and best combs from the old bottom story, and

Log gums in Alabama.

feeding sugar stores, was the first step toward putting the bees in a prosperous condition. I fed by turning ten-pound pails full of syrup and with cheap pie-tins over them bottom end up, placing them on top of the frames and setting empty hive-bodies over them.

All the bees had to do was to crawl over the edge of the shallow pie-tins to get the syrup, which they would generally do through the night if there were enough

of brood per swarm, one even having twenty-five frames of brood.

The spring was backward, and little nectar came in until the latter part of March. From then on a slow flow was on most of the time until the first of July.

July (the best honey month of the year) was a complete failure on account of a bad dry spell. Thus my crop was only 57 pounds per colony, spring count, with an increase from 364 to 560 colonies (increased mostly by division), and about 1100 pounds of wax. I had 8000 new wired Hoffman frames made into full-drawn combs. From thirty-five to sixty pounds of honey stores the latter part of August, and a slow but steady flow of nectar when I left for Michigan, gave me hopes of a successful wintering.

My section honey was mostly built over double ten-frame hives

A large force was necessary.

empty combs to hold it. I put small twigs under the pails so the syrup could run out. When there was not enough drawn comb to hold the syrup the bees went right to work drawing out foundation. Of course feeding had to be done at night.

To keep bees from robbing, while transferring, I built a screen tent to work under. Believe me, bees are always on the lookout to rob in the South—at least where I am located. The bee-moth will also ruin combs within eight or ten days if they are not left in the hives. So I winter all combs over bees.

Although many swarms were taking their midwinter rest from brood-rearing, and there were no drones when I commenced transferring, I lost only one colony transferred, and that by robbing in an out-apiary. I lost several from starvation in out-apiaries before I could get to them, as the heavy old hives made it hard to judge their supply of stores.

I transferred nearly 200 colonies in January and February, and also bought and transferred enough bees to make me 364 colonies, spring count.

A cool spell stopped the pollen supply, and also stopped brood-rearing right in the midst of my work; but when pollen again began to be carried in, brood-rearing started in earnest. By adding new hive-bodies filled with full frames of foundation I later had an average of fourteen frames

and that will be my plan for producing honey next year. Bees in the South need plenty of room in which to rear brood, and also to keep down swarming.

I build my hives with bottom-boards the same size as hive-bodies, so they will pack better in loading. The bottom-boards have a hole eight by ten inches through them, covered with galvanized screen and a sliding tin to gauge air-space or to close for spring brood-rearing. There is also a sliding metal piece at the entrance to gauge according to the season, or for protection from robbing. To move a swarm of bees several miles I have only to push in the front slide, see that the under slide is drawn away from the screen, load, and away they go.

For an alighting-board I make a small board and nail two pieces of bent sheet iron. This fits in the groove that the front slide fits in, and drone-traps are also fixed with tin grooves to fit in the same grooves in front of the hives, making them very secure, so the same combination works for all.

I have a frame made to hold two 8 x 10 glasses for a cover. This always fits the hive, making it bee-tight, and also allows one to see at a glance how bees are, without letting in cold air. Over this I have a tin cover to keep all dry, and, lastly, a wooden cover over all as a weight and a protection from the sun. This combination makes three air-spaces between the sun and the bees.

I hope the year 1915 will be a good season in which to test out my localities; and as I have as high as 200 colonies in an apiary I expect to make new locations next spring. This will give the bees a better chance.

With other apiaries besides my own in one territory, nearly 500 colonies can reach the same flora. There are nearly 900 colonies in a straight line of nine miles.

Marshall, Mich.

A PERAMBULATORY EXTRACTING EQUIPMENT

BY E. F. ATWATER

Some time in 1910 Mr. E. B. Metcalf, of New Mexico, described his portable extracting-outfit with which he handled the output of 1500 colonies of bees.

Two years ago I found that the use of a building at each yard for extracting, where very large crops are not the rule, is very expensive when more yards are added each year. Certainly for a district where heavy

a floor space 12 x 16 feet, 8 feet high, with large screened openings 3 x 8 feet on each side, making a cool place in which to work.

At the rear, on one side, is an opening in the canvas, 3 x 3 feet, covered by a large flap through which the supers of honey are put into the tent and are piled in long shallow pans. Through the door in the front end the empties are removed.

A portable outfit saves time and money.

crops are not the rule, a portable outfit is desirable, and a time and money saver; so we built an extracting-house on a first-class low-wheeled truck. The main floor is 7x16 feet, with sides 2½ x 16 feet, which are turned down when the yard is reached, and the tent can be quickly set up. This gives

There is ample room for several workers; and in robbing time, 100 full-depth supers of honey may easily be piled inside at one time.

The floor arrangement is illustrated.

The supers come through opening A; are piled along walls at BB; the uncapper (one

or two) stands at (C), uncapping into tubs DD (which have slatted frames or screens supported a little above their bottoms) and both draining into one can beneath. The tubs rest on a suitable framework so as to bring them to a handy height for work.

Plan of portable extracting-house.

The uncappers use steam-knives heated over the gasoline-stove E. Combs are set in drain-box F, without stopping.

From drain-box F the man at the machine puts the combs into the extractor. When extracted they are jerked out of the machine and piled on the edge of the can and cross-arm, the reel again being filled and started. Empty combs are put into supers which are piled at GG, and thence returned to the hives by passing them out through the front-end door of the tent.

The honey is pumped up about 6½ feet, then run outside through 2-inch hose, into tanks located near by. In case of a light extracting at the end of the season, the honey, if desired, may be run into a tank in the corner.

In this connection many a failure to get good results with the pump is due to faulty use. When our pump arrived we saw at once that there would be a great waste of power in expecting the pump to draw our thick western honey through the small hose or to discharge it through the small pipes sent for the purpose.

By reference to the tables used by plumbers it will be found that a slight increase in the size of a conducting-pipe results in a very considerable reduction in the retardment of the stream, due to friction between

the liquid and the pipe. We mounted the pump a little below the extractor and connected it with the extractor by a 2-inch suction hose, so that gravity carries the honey to the inlet of the pump.

From the pump upward we use about 1¼-inch pipe, and then carry the honey wherever desired, with a 2-inch suction hose. So connected, one's troubles with the pump are over, and its capacity is ample.

We mount the pump as shown so that the pump platform may be lowered to tighten the belt.

At the rear the 2 x 6 is hinged to the 4 x 4 block B, while upright 2 x 4's are slotted so long bolts will pass through both, above and below 2 x 6 A, to fasten the pump-platform at any height.

For a few yards, and not too many hives, a permanent room 9 or 10 x 16 ft., on such a wagon will answer nicely, and save some time in setting up; but for many yards the larger outfit allows faster work.

HONEY-PUMP MOUNTING.

A, edge of 2 x 6; B, end of 4 x 4; C, side of one of the slotted 2 x 4 uprights; CC, under E, position of the 2 x 4 uprights; H, the honey-pump.

Our only difficulty these last few years has been to get enough honey to work with. Such a portable outfit is far cheaper than an equipment at each yard, and there is far less robbing than with a building standing on the ground.

Meridian, Idaho.

Bees produced little more than winter stores.

AN OFF YEAR IN WEST VIRGINIA

BY S. MACDILLEY

In 1913 we were so hard hit by drouth that I don't believe any colonies in the county produced a surplus above what was required for their wintering. Last year conditions have been a little better.

The photograph showing half of my apiary was taken in August, before any surplus was removed. It speaks for itself.

We depend on locust and basswood for nectar, though wild flowers and apple-bloom play a small part.

Comb honey sells for 15 to 20 cts. a section. Extracting has not been introduced yet, as our local trade consumes all surplus.

Edray, W. Va.

BEEKEEPING IN JAPAN

BY S. IMAMURA

The beekeeping business in Japan has been carried on by my countrymen from very ancient times. The common Japanese honeybee is black, with a small body, a sting, and has all the evil characteristics of the common blacks of America.

Some people say that Japanese honeybees are of two kinds—one yellowish black and the other black. The history of the yellowish black is as follows:

Over 350 years ago a Christian priest named Francis Xavier came to this country, and at that time a foreigner brought some

yellow bees from Europe and stocked them on Okinawa Island (between Kyushu and Formosa). The result was not good, and the apiary soon vanished, but the brood spread over the southern part of Japan.

Some years ago Mr. K. Aoyagi imported some colonies of Carniolan bees and started an apiary at Hakone, and afterward imported several other kinds.

It is curious that, although different sorts of foreign bees will cross with each other, Japanese honeybees absolutely refuse to do so. That is to say, Japanese queens and

Apiary owned by M. Norikane, Tukutamura, Horasimaken, Japan.

drones will not mix with foreign drones and queens, and so they always retain their natural character.

In 1909 the president of the Beekeeping Association of Shimabara Peninsula was the governor of the peninsula, and in 1910 our association sent Mr. F. Nakamura to the Sandwich Islands, where he bought some colonies of pure golden Italians from Mr. Eph. C. Smith. The following year these colonies had increased to 150, and were divided among the members of our association.

In 1911 and the following year there was quite a rage for the Italian honeybee, especially in Gifu, Fukuoka, Rumamote, and Nagasaki Ken, and the price per colony advanced to yen 100.00 (\$50.00), and even reached yen 150.00 (\$75.00) at the height of the rage. This enthusiasm did not die

out till the beginning of this spring; but the price now is only yen 10—15 per colony.

Stocking of bees is not at all evenly distributed over this country, even in this small peninsula. Some parts are very much overstocked, and the other parts have not a single colony.

Modern beekeeping is quite a new industry in Japan, and at present beekeepers are rather colony-sellers than producers of honey; but I believe that in a few years the industry will greatly increase, and much honey will be produced. We have many honey-plants such as cherry, rape, jasmine, fruit-blossoms, live oak, wax-tree, buckwheat, tea-blossoms, camellia, and many others.

Nagasaki, Japan.

ADVANTAGES OF A SHALLOW BROOD-FRAME

BY D. W. HOWELL

I use ten-frame brood-sections, but have them only eight inches deep. This depth, I find, is better adapted to this locality, and gives more honey in the supers. When the bees are storing honey from the fall flow, and the queen is decreasing her egg-laying, this space is filled with stores for winter. The medium-depth brood-nest which I use

does not allow so much room for stores that we do not need to winter on here.

I make my frames $7\frac{1}{2}$ inches deep, and want them to hang flush with the top edge of the hive section, just as the shallow deep supers do. I then use 16 x 20 sheet-zinc queen-excluders which lie flat on top of frames and hive section.

Part of D. W. Howell's home yard.

The supers and also the brood-sections should have the bottom edge of the ends beveled one-half their width on the inside, which will do away with the trouble of having the ends of frames stuck to the bottom edge of the section placed above. When hive sections are made this way they are much easier taken apart, and fewer bees are killed in handling.

I am making and using a hive-stand 5 inches deep, 22 inches long on top, and

beveled to the bottom as the illustration shows. This allows the bees to have a good alighting-board when they drop with heavy loads. This stand is covered on top and front, also a strip is nailed in the back as a brace. On top of this cover is then nailed $\frac{7}{8}$ square strips on sides and back. The hive sections are then placed on these strips, doing away with the bottom-board entirely. All this should be given two coats of paint.

Shellman, Ga.

CONNECTICUT BEEKEEPERS TALK OVER PROBLEMS

BY L. WAYNE ADAMS, SEC.

The twenty-fourth annual meeting of the Connecticut Beekeepers' Association was held in the state capitol, Hartford, April 17, 1915. President Bunnell, in his annual address, mentioned the advantages of the association for learning by getting together. Non-members as a rule are indifferent and slack beekeepers; but members take more interest in bees. Last year was the poorest in his experience, for honey, but the most prosperous for the association. The field day last July was a grand success—ideal weather, good speakers, and excellent program, including the visit to the state prison.

A decided forward step was taken last

fall when President Beach approved of the plan to install an apicultural department at the Connecticut Agricultural College. This was advised by Mr. Augur in 1883, and is, at last, about to materialize. The college has seemed reluctant in the past to install beekeeping. Students will become interested, take home the ideas, and save the nectar from going to waste.

Dr. T. S. Seranton, of Madison, delivered a most interesting talk entitled "Beekeeping on the Farm Fifty Years Ago." Dr. Seranton is probably the oldest beekeeper in Connecticut, being 84 years of age. He has kept bees for 66 years. He once said that

Howell's hive-stands which do away with the bottom-boards.

he had kept bees over sixty years, and didn't know anything about them until the last twenty. He exhibited an ancient model of a hive known years ago as Hall's Self-protection hive. The "protection" was against wax-worms, and consists of two trap-doors in place of the bottom-board to be opened frequently to empty the wax-worms—the theory being, perhaps, that the worms live in the bottom of the hive and visit the combs only for food.

While he was still new in beekeeping, an improvement in hive construction came with an upper story containing boxes. This yielded ten pounds of honey—clean, and free from dead bees—such a curiosity that the townspeople called from miles around and viewed it with surprise. Hall's famous Self-protection hive was the next improvement, and with it came the inventor's book on bees, containing some of the following statements:

"The queen always lays queen eggs before departing with a swarm. The bees know the difference." "A queen can be made at any age by feeding properly."

Dr. Scranton exhibited an ancient frame which had a triangle-shaped top-bar with a sharp edge pointing toward the bottom-bar. This sharp edge served as a comb-

guide for the bees to build the comb exactly in the center of the frame.

Geo. H. Yale, third president of the association, read a paper entitled "Some Things I have Learned in Keeping Bees." He said he had kept bees thirty years. He began by purchasing a hive standing on end with cross-sticks inside. He brimstoned the colony at the end of the second year. One Sunday afternoon he captured a swarm by sawing down a sapling. His knowledge of beekeeping began at this time. The following year a swarm issued, and he captured two swarms at once on a sheet, placing two hives where he expected the swarms to separate and each chose a hive; but they both entered the same hive. He finally managed to separate them into two colonies. He has learned by experience that bees dislike woolen clothes, dark garments, and quick motions. Bees do better in hives facing east or south. He prefers some protection when hiving a swarm, and finds the bee-escape a great help when producing comb honey. King-birds and bee-martins, abundant when drones are flying, catch queens.

Allen Latham spoke on "Bulk Comb Honey." He uses starters instead of full sheets of foundation to avoid the thick

One corner of the Bonser apiary, near Conrad, Pa.: 111 colonies with young queens and in fine shape. Mrs. Bonser is foreman of the apiary, but Mr. Bonser is getting to be quite a beekeeper.

tough midrib. He prefers the long hive or "Let-alone," with seven or eight frames in front for brood-rearing, and twelve or thirteen in the back for storage, the frames running crosswise. When cutting out chunk honey he leaves the starter in. Bulk honey can be taken from the hive and put up at any time, but extracting must be done in warm weather. He uses frames with closed top and end bars. O. O. Poppleton's hive is quite similar, except for this feature. Bulk honey can be produced also in Langstroth hives by tiering shallow supers. Plenty of room in his hive keeps down swarming with black and Italian bees, but not with Banats. This hive is always ready for winter, and requires no packing.

Mr. Latham produced 180 lbs. from one hive in a poor season, and has frequently secured 100 lbs. He is satisfied with 60 lbs. per colony, but 30 lbs. or lower is a failure. Straining is the biggest problem he has to deal with—how to get the best results with the least muss. He uses a square can with a wooden frame fitted into the top, holding cheese-cloth, and above that a piece of wire netting three mesh to the inch. He uses a five-gallon can for mashing, and squeezed out between four-fifths and three-tenths of the honey, the amount depending on the length of time in waiting. The broken combs, placed in a dish-pan, he puts into the oven on the grate with a baking-tin

between this and the fire-box to avoid too great heat. He leaves it half an hour, and stirs occasionally. All of his best honey is treated this way.

For marketing he prefers to use one, five, and ten pound pails, and to sell from house to house. He cuts the combs flat on brown paper, puts three, five, or seven pieces, according to the size, into each pail; and then pours liquid honey over all of it. This should be marketed early to avoid candying.

"How I Cure Foul Brood, and Dr. Miller's Method," was the subject of a paper by A. W. Yates, foul-brood inspector.

Keep all colonies clean, and exercise great caution. Beekeepers should be educated about the symptoms and treatment. Italian bees are found to be the most nearly immune. Boiled honey can be feed with care, but sugar syrup is safer. Don't buy old hives or combs. Treat by shaking at night and during a honey-flow. Dequeening may be used also. August is the best time for dequeening and requeening. The disease will probably never be eradicated, but is often aggravated through carelessness and ignorance.

The most practical method of cure is by shaking into the old hive when the other hives are closed. Have everything ready before beginning. Take out two frames

Bee gloves and bee hat, the real thing.

and shake each frame into the hive, first putting a queen-guard on the front of the hive. Use carbolic acid to prevent robbing. Melt or burn all old combs, and burn the frames. If the colony is 20 to 25 per cent diseased, it is better to shake. The Alexander method modified by Dr. Miller—that is, dequeening and requeening—is all right in mild cases; but it is cheaper and safer to shake and burn the frames. The best time to requeen is when treating foul brood. American foul brood travels slowly, and is quite rare.

President Sherman E. Bunnell, of Winsted, presided. The secretary-treasurer's reports showed the association to be in a very prosperous condition, with a membership of 159, and cash on hand of \$109.33. This represents the high-water mark with the Connecticut association, with good

prospects of a steady and healthy increase. The officers were re-elected as follows: President, Sherman E. Bunnell, Winsted; vice-pres., Rev. D. D. Marsh, West Hartford; sec'y-treas., L. Wayne Adams, 15 Warner St., Hartford; executive committee, Lyman C. Root, Stamford; Stephen J. Griffen, Bridgeport; Henry W. Coley, Westport.

The secretary was directed to arrange for a two-day field meeting at the Connecticut Agricultural College in conjunction with the Connecticut Pomological Society, as it seemed that the members of two industries so closely allied should become better acquainted to the mutual advantage of both.

The association went on record, opposing, as dangerous, spectacular experiments with bees in public.

South Wethersfield, Ct.

SOME BEE STUNTS

BY J. D. FOOSHE

At our Georgia and Carolina fair I saw a man traveling with a carnival and constituting the midway of the fair. He was performing stunts with bees which would seem to contradict us in our observation of bees. While he did perform some wonderful feats, none of them could prove to a veteran that bees can always be handled as he handled them. In the first place, we all know that bees are always gentler and more

tractable in a house or tent than anywhere else. This man had a screen-wire tent about six feet square in which he operated. He is baldheaded, and has a hat with a wire around the inside to fit, so as not to let the hat come down on his head. He would scrape up bees with a paddle from a cloth and pour them into his hat, and carefully place it upon his head, but, of course, he was careful not to mash any. He would

also bounce a handful of bees and catch them as a ball; but all this performance came about by conditions, and not because his bees were gentler than any others. They were a fair sample of the three-banded Italians.

These stunts only go to show that persons from observation learn when they can handle the little pets with impunity. When I wish to extract honey I either use a house or tent, but recently a tent; and after getting my hives cleared of bees as best I can by shaking a frame I carry them to the tent and take off my hat and coat, and, as a rule, never get stung. I usually make a tent of mosquito netting about six feet square; and when done I take it down and put it away.

CONDITIONS IN GEORGIA.

I have been here about four years, and I have yet to see my first honey from asters and goldenrod. Where I moved from I nearly always secured a crop from this source. I do not know of any cause except a very dry atmosphere. Honey-plants will not secrete honey without moisture. Bees will work well on buckwheat here in the South, but I decided it did not pay for the honey. It blooms profusely, and bees work on it until about 9 o'clock; but I have observed that they gather more pollen from it than honey. It will not seed here unless some late; but when it comes to pollen, the ragweed has all the other plants beaten. It is the best pollen-producing plant that I know of, but has no honey.

Augusta, Ga.

Bees make a good chest-protector. Photographed by L. N. Gravely, Ringgold, Va.

DOES ALFALFA WITHOUT SEED GIVE NECTAR?

BY T. J. QUAIL

In a recent issue of GLEANINGS Dr. Miller says that he saw bumblebees working on alfalfa, and that the other bees were not working on it. While Dr. Miller is an expert beeman, I think he must have been mistaken, although the bumblebees may have been looking for honey. I have never known alfalfa to yield honey east of the Missouri River. Alfalfa blossoms that do not make seed, as a rule do not yield honey. I should like to know what the experience of other men has to present on the question. In Missouri I once saw a large field of alfalfa that was a mass of blossoms. The owner said he was expecting a heavy yield of seed, although there was not a bee to be seen on the blossoms. The owner harvested the alfalfa and started to thrash it. After

an hour's work with a big machine he did not get a pound of seed. Alfalfa and white sweet clover do well in central Nebraska, and often yield heavy crops of seed, although some years have very light crops. Alfalfa makes the best seed in dry years.

We often get 150 to 180 pounds of section honey per colony on alfalfa. In fact, alfalfa and sweet clover are the only honey-plants in this part of Nebraska. The bees get some honey in the early part of the summer from box-elder blossoms. We do not raise any clover or timothy here.

White sweet clover which has always been considered a noxious weed, is coming into the native hay-meadows along the Loupe and the Platte Rivers, where they are saving the seed. Farmers are now sowing

this so-called noxious weed for pasture and hay. A full carload of sweet-clover seed was shipped from a station in Nebraska last fall. One farmer in Nebraska sowed 600 acres in sweet clover last spring. Much of this land was sandy, and he got a stand of only about 300 acres. He will sow the other 300 acres in sweet clover this spring.

Bees generally winter well in Nebraska, either in the cellar or on the summer stands.

The cellars here are very dry—no dampness whatever.

The only drawback to beekeeping in Nebraska is a bee disease, not the regular foul brood. It will break out in a yard, and the bees do not swarm. It may last one or two seasons; and if the colonies are not requeened with young queens they become queenless and die out.

Miller, Neb.

TERM NOTES COLLECTIBLE

BY ARTHUR C. MILLER

Look on the sunny (and funny) side of things. It is the happier way, and leads to success.

Hundreds of hives of bees were shipped to California by water in the winter of 1859. D'ye mind?

Perhaps, just perhaps, some of the things we beemen *know* ain't so after all. I'm talking about the other chap.

Brothers Holtermann and Crane are scrapping over an eight-foot line fence. Humph! A fence that high would keep most folks apart.

The predicted fun has arrived. Sixteen-inch covers on sixteen and one-quarter inch hives! They do not exactly "fit like a duck's foot in the mud."

Procrastination is the—say it your way if you wish—what I was going to say, however, was that Procrastination is the trouble-maker and crop-loser in the bee business. And you might impress it on your bees too.

"If the bees are getting honey abundantly the boxes may be set a foot or two from the entrance to the hive for the bees to leave them. Keep from the hot sun."—Quinby, 1860.

Nice mess caused by the difference of a quarter inch in depth of different makes of "deep supers." It gives one violent thoughts if not angry speech. When shall we get standardization of supplies?

So my friend Byer thinks candy-feeding a fad. Well, son, you have a chance to think again; but give it a good try first—the candy, I mean. Candy has sundry and several advantages peculiar to itself.

What's in a name? "Absorbent cushions," which must not absorb, but shall permit the passage and escape of moisture. "Call a spade a spade" instead of a "dirt conveyor," and then the poor innocents will stand a show of getting the drift of what you are trying to talk about. A really *ab-*

sorbent cushion over the bees would be a sure-enough bee-extermiator.

Those Californians seldom do things by halves. They voted "wet," and now they have had superabundant rains, which means a good honey crop and plenty of dilutant for the other "wet" things. Blessings never come singly.

I wonder if F. A. Hanneman "invented" the perforated zinc queen-excluder, or merely applied to the art of bee culture the perforated zinc long used for bean-sifting. The results are all right, so we won't quibble about terms or glory.

Louis Scholl got caught with 35,000 lbs. of comb honey on his hives in winter, stuck there by the mud. Some of the New York boys will envy him. Wonder if Scholl and others would not profit by turning some of their energy to a good-roads propaganda.

Complete equipment to save labor is excellent, if it does not cost more in upkeep and interest than the labor saved is worth. Just where equipment should be curtailed and labor be added is a mooted question which each one must decide for himself.

In ye olden time a split side stick, with the pith partly removed to form a trough, was filled with a mixture of ale and sundry other things, and pushed in at the hive entrance to feed the bees, to keep them alive and "to give them encouragement." Wonder what some of those old sages would think of the manner of its doing now.

Who invented comb foundation? Don't answer too quickly. Listen. "A gentleman just in from California informs us that in San Francisco there is just now no little interest taken in a process of casting the bottoms of the cells of honeycomb from old wax. He says the bees will go on and complete the cells, and that this process not only furthers their work, but secures regularly formed combs in any position in the

hive desired."—*American Agriculturist*, May, 1860, page 154. Wonder what any of the "old boys" of California can dig out for us on that?

Ever watch the bees trying to go through zinc or wire excluders? Tee hee! They claw the air like a bug on a pin. Funny, and yet one pities the poor little cusses. Two spaces (three wires) with the outer wires let well into the wood slats, and the slats nearer half an inch thick are different. Two rows of holes in zinc plus *thick slats* are also different.

It is pretty safe to say that most of us might lessen the labor item if we could see our work as others see it.

It is also safe to say that no small part of the labor-saving can be effected with the equipment we now have on hand, if we will only lay aside all prejudices and try the other fellow's ways until we prove whether they are any better than ours. It is barely possible that they may have a few kinks which are worth while.

Building up weak stocks, fussing with dwindling ones, getting queens into those with laying workers, and a whole lot of other things, seem like bugbears to all novices and to many an older hand. Does not all the bother and worry start with poor beekeeping? And are not the text-books and journals somewhat to blame for laying so much stress on those problems? Annihilate all such stocks and prevent their occurrence thereafter, if you can, and you can most of the time.

Did I hear some one say "more ventilation needed," and some one else say "easier access to supers"? Um! Easy access?

Ventilation? And yet big colonies store up big crops through two holes of a zinc excluder. And there is a chap out west—I think it is Atwater—who uses honey-boards with solid middle, and only a row of holes near each outer edge. But there, there! I didn't intend to ask any awkward questions—oh dear me, no!

Dr. Miller is strong on large entrances. Some of the rest of us are also, but it took us quite a while to learn their value. If you try them, be sure to back them up with strong colonies just as the doctor does.

Food for bees is pretty much the same sort of question as food for other creatures. The answer is modified by such factors as time of year, time at operator's disposal, results desired, strength of colony fed, utensils at hand, etc. Syrup is best at one time, soft sugar at another, and candy at another. Soft sugar calls for the least work, syrup next, and candy most, so far as preparing the food is concerned. Syrup is less economical than candy or soft sugar, and the two latter are about on a par. Soft sugar is not in convenient form for winter feeding, but candy is. A thin slab of candy can be laid on top of the frames at any time, but syrup and soft sugar call for feeders of some sort.

Pshaw! What is the use of enumerating further? Go try them all, and you will soon use one for one time and purpose and some other at another. You will never entirely abandon any of them—unless you get into one of those "poor locations" of Illinois where they get an average of only 266 sections per stock.

Providence, R. I.

MICHIGAN JUBILEE ANNUAL MEETING

BY F. ERIC MILLEN
Secretary-treasurer

The oldest beekeepers' association in the United States will celebrate its fiftieth anniversary at Grand Rapids, Michigan, December 15 and 16.

The original records of the association, still in good shape, show that Professor A. J. Cook, now State Commissioner of Horticulture for California, was the first secretary of the association. At that time Professor Cook was connected with the Michigan Agricultural College, East Lansing, Mich., teaching entomology and apiculture. For over twenty years since Professor Cook left, beekeeping has not been taught at the college; but in 1913 I had the pleasure of

introducing the subject once more. It is a coincidence that the present secretary of the association, after so long a lapse, is connected with the Agricultural College, trying to disseminate the subject of beekeeping, as was the original secretary.

Looking over the records we find the names of many prominent beekeepers who have since gone to their reward. Among others these names are found: Ezra Rood, the first president; Bingham, Gallup, Otis, Taylor, Hilton, Hutchinson.

In one of the early meetings I find that a paper was read by the secretary on "The Apiary and its Arrangement," by A. I.

A partial view of the apiary of John R. Powers, Shelburne Falls, Mass.
Mr. Powers stands at the left in the picture.

Root ("Novice"). I wonder whether Mr. Root can remember this paper. Besides Mr. Root's, many other names are prominent—one other, who is still alive, Mr. M. M. Baldrige, who read a paper on "The Extractor."

We hope to have many old memories revived at Grand Rapids, so that we present-day beemen may get a glimpse of what the pioneer beekeepers had to contend with.

The association is trying to arrange a meeting that will be a little out of the ordinary; and, with the co-operation of the

Michigan beekeepers, this should be possible. We aim to make a special effort to get a good exhibit of honey; and any beekeeper who would like to make an exhibit would do well to write me. By making plans at this time the choice of the crop can be saved and a nice exhibit prepared.

We shall be pleased to receive the dues of any members who have not paid, and from others who would like to join the association. In a future issue we shall have more to say.

East Lansing, Mich.

PLANTING SWEET CLOVER FOR BEE-PASTURE

BY E. M. NICHOLS

Mr. John R. Powers, the village beekeeper of Shelburne Falls, Mass., plants sweet clover for his bees. The clover shows in the background of the picture. Seed was planted several years ago, and comes up each spring. The plants are very thrifty, and average in height about six feet. Compared with the height of the men, this does

not seem to be the case, but the illusion is due to the fact that the men are standing on a raised platform.

I have grown a little clover myself for the bees, and find it worth while for that purpose alone. It yields honey for a long time, and is particularly valuable for the queen-yards.

Lyonsville, Mass.

THE ISLE OF WIGHT DISEASE

BY GEO. W. BULLAMORE, F. R. M. S.

An attempt has been made to represent the Isle of Wight disease as something new; but the literature of beekeeping in England affords evidence that a disease similar in its effects has from time to time ravaged the apiaries of this country. Letters written to the press during the exceptional mortality among bees in the early 'sixties of the last century describe symptoms identical with those of the present epidemic, and also show that the trouble then had been known for years as a peculiarity affecting the beekeeping in certain districts.

The Italian bee and the bar-frame hive were both introduced here in 1859, and trading in bees followed. There is little doubt that this trade has much to do with the severity of modern epidemics.

Much "beekeeping" in this country is less concerned with keeping bees than in persuading others to do so. Accounts of losses were therefore suppressed owing to their discouraging tendency. An Isle of Wight beekeeper was the first to break through this conspiracy of silence, and, as a consequence, the disease became notorious as the Isle of Wight disease.

I have read thousands of descriptions by other beekeepers, and have observed many cases myself. Beyond the death of large numbers of bees no symptom is present invariably. While confined to the hive by severe weather in winter the bees drop dead in a heap on the floor-board. In milder weather they may crawl out

and die on or near the alighting-board, which is sometimes soiled with light or dark signs of dysentery. At seasons when much activity prevails among the bees death may occur while they are out gathering. The dying bees may then be found under flowering trees, on blossoms in the fields, or crawling about on roads and paths. The symptom that usually attracts attention is numbers of crawling and dying bees in front of the

Microphotographs of *Nosema*. Reproduced by permission, the Board of Agriculture and His Majesty's Stationery Office.

hive. These bees crawl up blades of grass and sometimes get together in small clusters. Crawling is an indefinite term used to denote moving slowly, running swiftly, or advancing by short leaps in attempts to rise on the wing. The bowel in a crawling bee is often, but not invariably, loaded with pollen residues.

Stocks or swarms, apparently healthy, from the same affected district, when placed several miles apart have been known to manifest this crawling symptom on exactly the same date many months after their arrival among new surroundings. Stocks may store abundant surplus, and show no signs of disease during the summer and autumn. Shortly after being jacked down for the winter they have died. The facts suggest that the *apparently* rapid spread is due to similar conditions acting on disease latent in a large number of stocks.

Epidemics in this country coincide with spells of wet years, and a wet breeding season appears to be an important factor in favor of the disease.

Queens, drones, and workers are affected. The queen often survives the workers, probably on account of her greater vitality. When her death precedes that of the workers the crawling symptoms usually disappear so that queenless stocks are not suspected.

I have seen stocks exterminated when no sign of brood disease was present. Sealed brood from a moribund stock, when placed in a wire cage and incubated, has hatched out successfully.

Microscopic examination usually reveals the presence of parasites in the cells lining the stomach of a crawling bee, and these

parasites are believed to be young forms of *Nosema apis*. Spores of this organism are less commonly met with in this country.

A "Report on the Isle of Wight Bee Disease" was issued by the Board of Agriculture in May, 1912; and by permission of the Board and of His Majesty's Stationery Office I reproduce some micro-photographs of *Nosema* and also a map illustrating the spread of the disease in a small heavily stocked area. On this map the apiaries which developed the disease in 1909 are represented by black squares; those which developed the disease or died out in 1910, by stars; and those which developed the

How Isle of Wight disease spreads in a small, heavily stocked area. Reproduced by permission, the Board of Agriculture and His Majesty's Stationery Office.

disease in 1911, by black circles. The apiaries marked as concentric circles were apparently healthy in 1911, and four were removed from the district. Of the remaining eleven apiaries ten developed disease in 1912.

Bees which wander to other hives are probably the chief agents in spreading the trouble. Stocks in high trees, roofs, etc., being out of the line of flight of stranger bees often escape for a time. It will be seen by the map that stocks in the open suffered before those surrounded by fir-trees. Bees are more likely to fly around a wood than through it.

Some facts tend to disprove the view that frames and hives carry the disease. But it is impossible to imagine that an organism that is passed from bee to bee is not sometimes transferred indirectly by the agency of combs, etc. The explanation may be that, when parted from its host, the causal organism quickly loses its virulence or even its vitality.

Drug treatment is a waste of money; but, owing to the fluctuations of the disease, any quack remedy can obtain testimonials.

Stocks of foreign origin sometimes survive when the native bees die off rapidly. This tolerance or immunity is not absolute; and on the Isle of Wight, where the disease menace was constantly present, Italian and other foreign races died. To what extent this seeming immunity can be utilized for restocking is not yet known. In my own apiary all native blacks died out, and the

sole survivor of them was an Italian stock. Beekeeping can still be carried on, but will be in the future a matter of experience rather than dogma. It is too late now to attempt to stamp out the trouble. Owing to the manner in which the disease progresses before showing itself it would be necessary to destroy the stocks for several miles round any outbreak, with the result that these denuded areas would overlap and cover practically all beekeeping districts.

Statements regarding Isle of Wight disease made in GLEANINGS for controversial purposes should be received with reserve. John Smallwood (1914, p. 56) suggests that the disease is abating in Oxfordshire. The season of 1913 was there marked by heavy losses; and when his article appeared Oxford and district was practically cleared of bees. W. Herrod, p. 58, 1914, says, "Neither queen nor brood is affected, because their food . . . does not contain the germs of microsporidiosis." This is the scientific name for the nosema disease, because nosema is a protozoon belonging to the *Microsporidia*. Nosema has been found in queen bees by both Zander and Maassen in Bavaria, by Nussbaumer in Switzerland, and by Dr. Graham-Smith and others in England, as stated in the Report of the Board of Agriculture. If infected food is necessary to produce infection in queens, then I fear there is no alternative but to consider that digested food may contain "the germs of microsporidiosis."

Albury, Herts, England.

A NEW COLONY-RECORD SYSTEM

BY W. E. WOODRUFF

Like most beekeepers who run outyards I have found it difficult to keep tab on the condition of my hives and to remember what each needs. The card-index and notebook systems are too fussy for extensive work, while placing brickbats and other signals in certain ways on the hives is out of the question where one handles a number of colonies.

It occurs to me that a simple device, and one that would prove to be both inexpensive and permanent, would consist of an aluminum strip made in a semi-circular form and bearing numbers up to, say, ten, or, better still, having raised letters or words on it indicating the condition of the colony when last inspected. The following sketch will better suggest my idea. A pointer, or possibly two, should be tacked at a

point where they could be moved to the word or figure indicating the condition of the hive. In case numbers were used, the

apiarist would, of course, have to memorize a "key," so they would be intelligible.

Cottonwood, Ariz.

COMMENTS FROM THE COTSWOLD HILLS

The Value of Shelter in the Beeyard

BY A. H. BOWEN

A well-sheltered apiary is a great asset to successful beekeeping. Not only do the bees winter better and with less loss where the hives are adequately protected, but brood-rearing is started full early, and colonies will build up almost twice as fast as they do in an exposed apiary where there is little shelter from the elements.

On the Cotswold Hills we think the ideal location is a clearing in a plantation or spinney, where the undergrowth around is sufficiently dense to break the force of the wind and render the air warm and still, even in the chilly days of winter. With the hive facing south they

catch the full rays of the sun, and in the spring the bees can visit the water-trough or box of pea flour with perfect safety.

A sheltered nook within a copse the ideal location.

Moreover, a sheltered apiary is ahead of an exposed one all through the season. Manipulations can be carried out in comfort, while the bees are invariably better tempered than where a breeze is blowing around the hives and driving the bee-veil against the face of the operator.

Especially is protection necessary in a queen-rearing apiary when the bees are frequently examined. Furthermore, a sheltered situation near

the apiary affords an opportunity for the mating of queens in restricted mating weather, when the outside temperature is low or a strong breeze is blowing.

Shelter is so important that, in starting a new apiary, I would certainly give the preference to a well-protected spot. The cut gives a good idea of an English apiary with a natural windbreak.

Simple uncapping-box.

A SIMPLE UNCAPPING-BOX.

I have designed an uncapping-box well suited to the needs of smaller bee-keepers who work only a few hives. It fills all the requirements of a good box, and at the same time is simple and easy to construct. The illustration makes this plain.

It can be made from any drygoods-box, measuring about 30 inches long, 15 wide, and a foot deep. A piece of tin, 18 inches wide and as long as the box inside, is bent to form a trough which rests on the bottom of the box, the sides being made secure by nailing along two strips about half way from the top edge. This also gives support to five lengths of stout hoop iron upon which is laid a screen of large-holed perforated zinc for the cappings to drain.

The box is slightly raised at one end, so that the honey readily flows down and out of a one-inch hole at the opposite end into a tin placed underneath for the purpose.

When the cappings have thoroughly drained they are taken out and set aside ready for melting into wax.

The second sketch shows a device for confining the bees when hives are being moved. From a strip of wood 3 inches wide and the length of the entrance a piece

2

Device to confine bees en route.

is cut out of one side about an inch deep. Next a strip of perforated zinc or wire cloth is tacked along to cover the portion cut away. In order to confine the bees the guard is fastened zinc side inward to the hive front with two screws.

Such an appliance saves a great deal of time and many stings when preparing bees for shipment, and is much simpler to fix than the old type of "push-in" guard of wire cloth.

Cheltenham, Gloucestershire, England.

SPECIAL METHOD OF WIRING FRAMES

BY J. S. TAYLOR

With my method of wiring frames I can do as many as fifty an hour, although that leaves no time to spare and not many snarls to undo. Forty or forty-five are quite easily done, and, best of all, with not one-tenth the tedium of the old way. I find it hard to believe that this or some better method is not in use by the large beekeepers.

My method, in brief, is as follows: Start wire at hole B, then back through hole A; hitch it around the nail X, and drive the

nail home. Take the other end through C, then back through D; grip it with the pliers in the right hand; hitch it around the nail Y, and drive it home. Break off the surplus wire and release the frame from the vise with the left hand.

In nailing frames together I always leave the nails X and Y projecting about a quarter of an inch. I also run off the wire, cutting to length, without straightening too much or taking the coil out. The wires will recoil very nicely as a rule, and lie flat in an empty foundation-box.

Any vise will do. Note the small support for the end of the frame. This gives a solid rest for driving home the nail X. The vise takes the shock of driving the other nail.

As for the final drawing of the wire to the desired tension, I presume the reader will see that, with the pliers held in the right hand, and using the left as shown in the A B C, one can draw the wire as tight as a fiddle-string, provided the frame is firmly held in the vise.

Richwood, Ont.

WANTED—SOME BEEKEEPERS

BY W. J. ROUNDTREE

Referring to your editorial, page 260, March 1, "Beekeeping in the Great West," I want to say that we have here some virgin territory that is practically untouched. There are thousands and thousands of acres of alfalfa on irrigated lands, and sweet clover on all the roadsides and ditches, all wasting its sweetness on the desert air. It is not everywhere that additional beekeepers would find a welcome; but I would welcome some additional beekeepers here in Wyoming for the following reasons:

Beekeeping is in its infancy. There are only a few small producers with from 30 to 50 stands. We produce more honey than the local market will consume, but not enough to make a combined shipment of a carload. Freight rates are such that we cannot ship in any other way.

This territory is irrigated by a government canal known as the Pathfinder Project, which waters some 150,000 acres of land in the valley of the North Platte, in eastern Wyoming and western Nebraska. I hold no brief for the people of Nebraska, and do not know whether they would welcome more beekeepers or not; but here in Wyoming there are over 30,000 acres of alfalfa land in which I do not think there are 200 colonies of bees. Neither have I any bee locations to sell nor any ax to grind, except that personally I should like to see enough honey produced so we could ship to market in car lots.

The altitude of this valley is 4200 feet.

The climate is about that of Colorado. The land is particularly adapted to growing alfalfa. Sweet clover grows whenever it is permitted to establish itself, but is not cultivated as a crop. These are almost the entire sources of nectar. The honey is as fine as can be produced anywhere.

Winters are usually bright, dry, and not excessively cold. My bees winter in single-walled hives without protection, and so far my loss has been insignificant. Without having investigated the matter enough to say positively, I think locations can be secured up and down the river from Old Ft. Laramie to the state line. Possibly, also, below in western Nebraska.

So far we produce only comb honey. The percentage of increase in Wyoming has been very large in the last few years. There are no expert beekeepers among us as yet, and I do not know just what the yield is per colony. The government, I believe, gives it at 75 lbs. At Wheatland, in Platte Co., they have shipped a carload for the past two years; but that territory has been settled longer than here. The past few years the cultivation of sugar beets has cut down the acreage of alfalfa somewhat, but still there are thousands of acres, and always will be, since the crop rotation here is sugar beets three years, and then back to alfalfa again. I think there is a great future here for the bee.

Lingle, Wyo.

CATCHING AND CLIPPING QUEENS

BY E. S. MILES

Presuming that all up-to-date beekeepers, and all beginners who wish to succeed, practice clipping, and that some may not have a satisfactory way, I wish to give my method. While, doubtless, there may be better ways, if any one is not satisfied with his present practice let him try this one.

Queens are clipped primarily to prevent swarms lodging in tall trees and other inaccessible places; but I would clip so as to know absolutely without mistake the age of my queens, even if there were no other reasons. I want longevity in bees, and it seems reasonable to me to expect it from strains whose queens live long rather than from those whose queens are shorter lived. There may be other ways to mark queens; but as this is easy, effective, and at the

same time gives a chance for absolute control of the colony, and, so far as my observation goes, does no harm, I think it advisable and profitable.

When I started clipping I caught the queen by the wings with the right hand and held her with the thorax between the thumb and first and second finger of the left hand while clipping. It made me rather nervous to hold her this way, as I was afraid I might squeeze her too hard. At this time I happened to read that the bees would be more likely to attack and kill a queen held in the fingers, on account of the strange scent left upon her, and that the only way was to clip her as she walked on the combs. I wish that writer had told us to try it on drones or workers for a dozen times or so

first, for I tried it at once on a fine \$2 tested queen. Well, I clipped her all right, but not the wings; and I voted that way too expensive for me. So, in thinking the matter over I hit on the following way which I have liked well enough to continue ever since. I never have a queen lost from clipping.

To clip now, I open the hive as carefully as possible, so as not to alarm them, as it is easier thus both to find the queen and to catch her. When the queen is seen I set the left-hand end of the frame on the edge of the hive, or, more frequently, on my left knee, as I always sit when clipping, thus freeing my left hand. Catching the queen by both wings with thumb and fore finger of my left hand I set the comb back in the hive by letting the free end down until the projecting top-bar comes to the rabbet, then lower the end I have hold of till the bottom of the frame rests on the other end of the hive, the frame thus hanging in the hive at the left end, and projecting out at the right end. I now take the shears, which are laid somewhere convenient to my right hand, and lower the queen until her feet touch my left knee, when she grabs hold and begins to pull; and as soon as her legs are thus engaged, and out of the way, I slip the point of the shears over whichever part of either wing I wish to cut, and just a second glance to make sure her legs are on my knee—*snip!* and she is clipped, and running around on my knee, while the only part I have touched is between my thumb and finger.

I immediately set the point of the scissors down flat across her pathway, and, as she starts to crawl over them, I quickly transfer her to the top of the frames she came from. If she starts to run up the scissors I take them in the left hand, if necessary, to prevent her reaching my right hand before she is over to the comb; and it is a good idea to hold your free hand under her in case you should drop her off.

A little practice, however, will enable one to clip very quickly, and without touching the queen. As to her running on my knee, it is covered with propolis where I rest the

frames while catching the queen, so it is hardly likely she will get any hostile scent there. At least I find this entirely satisfactory; but one could rest her while clipping on a piece of board held across the knees if he prefers. Any kind of fine-pointed scissors that cut well at the points will do to clip with.

After clipping, close up the hive as quietly and quickly as possible. A young queen just commencing to lay is much more "scary" about being caught than an older one.

There is a little knack, also, in getting hold of a queen by the end of her wings. I am not sure I can describe it so it can be understood, but I'll try.

Most queens, when the fingers get close to them, take alarm and begin to run one way and another; and if you follow up they usually get very much alarmed, especially young queens. Now, if you try to grab a running queen with finger and thumb apart, you stand a good chance of striking her body, and perhaps injuring her. The way I do is to get her, or let her get, with her head up, and slightly away from where the fingers will be when I take her, and hold my hand as near her as I can without making her run. When I consider her in a favorable position I slip my hand quickly up to her with my thumb and fore finger tightly together; and when the points of them are close to her wings I roll my thumb and finger ends together by crooking my finger and thumb slightly, thus rolling the edge of my thumb and finger on to her wings with a sort of rolling or pinching motion. Without opening them apart I avoid danger of grabbing the queen's abdomen.

Practice on some drones, or young workers, and the knack will be acquired easily. In clipping, always handle combs quietly without jarring, and do nothing to frighten the bees. Keep cool yourself, and don't be nervous. If you cannot do this a little practice on drones or workers may help. It is perfectly simple and easy after you have had some practice.

Dunlap, Iowa.

HIVING AND CARING FOR RUNAWAY SWARMS

BY JEAN WHITE

It sometimes happens that a runaway swarm of bees settles in a spot where it might easily be hived if one knew how to go about it. If one does not know, the swarm will fly again when its scouts return, and

locate in a hollow tree and be lost forever. The process of hiving is simple enough so that any one might safely perform it; but often a novice with bees has not the courage. Bees settle most often on the branch of a

tree, although not always. They have been known to settle on almost every known thing that would offer them a chance to hang. If they settle on something where the swarm is pendulous, and not too high up, the process of hiving is very simple.

Protect the head with a veil, being sure it is well wrapped about the neck and stands away from the face somewhat. Any good-sized hat-veil will do, if tied around a hat with rim enough to hold it away from the face. Protect the hands with loose kid gloves and tie the sleeves over the wrists; for if a bee starts up your sleeve or down your back you will attend to nothing else for a time, very likely. Get a good big pail with a bail; and, holding it under the cluster, pull them carefully off the branch into the pail. A box will do, but is not so easily handled. Having them in the pail, cover them over with a thin cloth tied down, and get a hive ready. They may remain in the pail or box for some hours, or even over night if the cloth covering is thin enough to admit plenty of air. Mosquito netting is about right; but cheese-cloth will answer. If possible to find a modern hive and some foundation, put strips of foundation along the edge of the frames. Set the hive on some kind of firm support that will raise it a few inches from the ground, and face it toward the south or east, so that the early morning sun will warm the entrance. Place a board close up to the entrance; cover it with a white cloth; and when all is ready empty your pail or box or bees out upon this cloth-covered board close up to the entrance. Of course you will want to wear a veil and gloves to do this. Usually they will begin at once to crawl into this new hive-entrance. If they do not start, brush a few of them lightly toward it. After a few of them have gone in, the others will follow in a steady stream until all are in. With frames and starters of foundation they will not come out, but at once establish themselves and proceed to their business of building brood comb in which to rear a new crop of bees.

If no hive is to be had, a box may be made to answer, although, like all make-shifts, it is not so good. A box about twenty inches square and from eight to twelve inches deep may have the bottom removed. Saw out an entrance about six inches long and half an inch deep. Find a bottom-board that will allow of a four or five inch margin all around, and, having set this on something to raise it off the ground a few inches, turn the box with entrance down and toward the east or south upon this bottom board. You will have no frames or founda-

tion unless you manufacture frames, which you will hardly care to do. Make a cover for this box that will fit down tight, but that can be easily raised. Place inside a few lumps of sugar, and cover with a piece of oilcloth, as the box will hardly be waterproof. Let the oilcloth (an old table-cover will answer) project a couple of inches all around, and then place the cover, and weight it with stones or old iron so that the wind will not blow it off. Your house is now ready for its occupants. Proceed as with a new hive.

It is well to watch them for a few days to look out for signs that they are not satisfied with their new home. If they are, you will hear only a mild hum. The field bees will be busily going to and fro, and there will be a constant succession of little pollen-carriers going into the hive with their pollen-baskets so loaded with yellow pollen as to make them very awkward about crawling into the hive. This shows that they have begun work on their comb, and will stay. Should these pollen-carriers be absent, and the hive noisy and excited, with bees clustering around the outside, they will be quite likely to come out and seek other quarters. Sprinkling them with a fine spray of water will usually quiet them, and they will not come out if there is a big noise about. Putting lump sugar at the entrance, and covering them over with a screen, will induce them to get busy at home; and once they begin work they will remain. They seldom come out after the second day.

If it is early in the season, and the swarm a large one, they will want a chance to store surplus honey, or they will cast a swarm which is not desirable so late. As they must first build brood comb there will be plenty of time to get a super or a shallow body for extracting honey with frames and starters of foundation. It is best for a beginner to buy a body all prepared. After that one will know how to prepare one himself, and the expense will be somewhat less. In a home-made hive the bees having no frames or starters will build their comb very irregularly. They will winter all right indoors in this, however, if they have plenty of food. Take them in at the first hard frosts, and store in a dry cool cellar; and if it is not dark, shade the hive and entrance.

I got my start with bees from a swarm that settled on a shade-tree in the yard. I have had a good deal of enjoyment, some honey, and an increase of bees since then, and am very much in love with the work. Bee literature is as fascinating to me as the most enthralling novel.

Some Factors Governing Stimulative Feeding

Dr. C. C. Miller:—I have been thinking about this question of stimulative feeding a great deal, and I have wondered if there is not an explanation somewhere as to why some say it is entirely wrong, and others claim it to be the only thing.

My experience has been that, when the bees have plenty of sealed honey in the spring, they will raise all the brood they can cover. This is all I care that they should have. But now I am told that if a cold spell should come, and the bees have plenty of sealed stores, but none unsealed, they will starve the brood before they will uncup any honey, even though their combs are half full. Now, if this is true it seems that it would pay me to feed every colony some syrup when a cold spell comes in spring to make sure that none was without unsealed food. Of course, if the bees had gathered honey in advance it would not be necessary to feed. Then the large beekeeper with scanty spring pasture and danger of cold spells is the one who would profit by spring feeding. I believe that those who claim they profit by stimulative feeding in spring do not gain by stimulating the bees to rear more brood, but by getting them to keep what they already have.

Elroy, Wis.

OSCAR RITLAND.

[Dr. Miller replies:]

I don't know all about it, but I can tell you how it seems to me. According to your view the argument for the advantage of stimulative feeding is

that "if a cold spell should come, and the bees have plenty of sealed stores, but none unsealed, they will starve the brood before they will uncup any honey, even though their combs are half full."

What testimony have we in regard to this? Here is one item that may have a little bearing: I have often seen, in the fall, eggs in the hive and no unsealed brood, with abundance of honey in the hive; and I think this is a more common condition than is generally supposed. It seems to show that at least sometimes there may be plenty of stores in the hive, the queen may be laying, and yet no brood will be developed from the eggs, and of course no larvae fed, because no honey is coming in at the time. I have also known other times when the bees continued to rear brood, although for a number of days no honey had been coming in. This latter was in the early part of the year—not in the fall.

So it would appear that the season of the year is a factor in the case. Perhaps a stronger proof of this lies in the fact that it is not an uncommon thing for brood-rearing to be started before bees are brought out of cellar, when, of course, no honey is coming in, and at a still earlier date in colonies wintered outdoors; while it is well known that it is very difficult to start brood-rearing with any amount of feeding late in the fall.

It sometimes happens in winter that bees use up all the stores within reach, and starve or freeze with plenty of stores in the hives. But this happens only in a prolonged cold spell, for bees are provident creatures; and when they have used up what stores are within reach, unless it is too cold for them to stir they make it their first care on finding the nearby stores exhausted to bring a fresh supply from more distant combs, or else to move bodily to them. Moreover, I think they are not merely satisfied with sealed stores; and I am not sure I ever found a case when, if they had any honey at all, there was not a goodly store of unsealed honey in the middle of the cluster.

Now, keeping all these things in mind, and remembering that stimulative feeding is practiced, not at a time when bees are marooned with the cold, but when they are free to move to any part of the hive, does it look reasonable to suppose that with honey in the hive bees will let brood starve at a time when they are naturally most inclined to brood-rearing? I do not say that it never happens; I don't know; but I do say that in an experience of more than half a century I never knew it to happen with my bees.

Incidentally you raise the question why some think stimulative feeding entirely wrong and others claim it to be "the only thing." That's easy. Notwithstanding the strong inclination of bees to rear brood early in the season, a dearth will stop brood-rearing if the dearth continues long enough. In places where this occurs, which I think are exceptional, stimulative feeding is "the only thing," while in other places, such as mine and almost certainly yours, it does no good and may do harm.

Marango, Ill.

Doubled-up Nuclei Not Wintering Well

In regard to the wintering of bees in this locality, there has been a wide variation. I have visited perhaps a dozen beemen, and find where there was a fall flow of honey or where bees were located in a basswood belt the colonies came through the winter very well with but little loss. Buckwheat having been a failure last fall, most bees suffered as there was little if any brood reared after August 1. Our own loss was 8 to 10 per cent. This loss was chiefly among nuclei which were doubled up late in the fall. We did no feeding at outyards last fall, and the loss

here could have been avoided in almost every case by liberal feeding; but sugar was rather high, and we thought we would risk them.

There are many colonies which wintered in the ordinary eight-frame dovetailed hive with no packing whatever. In many cases these unpacked colonies seem to have wintered better than those heavily packed on all sides and top. It is beginning to bother us to know whether to pack or not. In one of our outyards we had a colony in an old-fashioned chaff hive. This hive got badly wrecked by stock after our last visit. It contained no chaff, and the sun could shine in on the bees when we found them. The bees were flying from all four sides at the top of the hive, but the combs were nice and dry, and the bees themselves in the best of condition.

Bellevue, O., April 20.

H. G. QUIRIN.

[We have observed a somewhat similar state of affairs in and near Medina. We find this, however, that the main cause of bad wintering is uniting up nuclei in the fall, pulling out pounds of bees from the colonies during the season, taking queens away from them, and otherwise disturbing the normal trend of the colony. In fact, general queen-rearing operations, the filling of orders for bees and queens, so demoralizes an apiary that it is in very poor condition to go into winter quarters. While these nuclei can be united they do not seem to get together in such a way that they will winter well nor come out in the spring in good condition. On the other hand, colonies whose brood-nests have not been tampered with, and which have been left through the entire season, and only the upper story or super taken off with honey, seem to winter well whether in double-walled or single-walled hives. But we notice this: That the same colonies in double-walled hives are a great deal stronger than those in single-walled hives. In one apiary where we found a large number of colonies had wintered in eight-frame single-walled hives they came out in very good condition. —ED.]

Apiary Demonstrations in Ontario in 1915

Arrangements are well advanced for the apiary demonstrations to be conducted throughout the province of Ontario this coming summer. The increased attendance of this last year indicates the great interest that is being taken in this line of work. In all, fifty-five demonstrations, with an average attendance of thirty-four, were conducted this past season. The whole apiary and the beekeeper's equipment is placed at the demonstrator's disposal, giving him excellent opportunities to illustrate with the actual objects many of his remarks.

The demonstrator has complete charge of the meeting. Usually he starts by a short talk on foul brood, then proceeds to the apiary and examines several colonies. If the disease is found, a colony is treated. Suggestions are offered on many minor details that present themselves as the hives are being opened. Special attention will be paid to wintering. Models of the four-hive wintering-case will be supplied the demonstrator. These will form a new factor of the meetings.

Final arrangements are yet to be made; but ample notice, both by post card and newspaper announcements, will be given later. G. F. K.

Beet and Cane Sugar Give Equally Good Results

As I stated some time ago, my bees were fed heavily last fall on sugar—some altogether on cane sugar, some altogether on beet sugar, and some half on cane and half on beet sugar.

I have not had time yet to make an individual inspection; but from casual observation there appears to be no noticeable difference due to the different food. Out of 180 colonies after 144 days in

the cellar, up to date only three are short and these proved to be queenless.

The hives all came out clean except one, and are in good condition. This one had no beet sugar. Three-fourths of them were heavy enough to winter again when they were taken from the cellar April 7. The first week was pretty cool, with freezing nights; but since then the weather has been ideal, and the bees have done well on soft maple, elm, plum, and dandelions, which are beginning to bloom now.

The clover wintered perfectly, but is in need of rain, as it is getting very dry.

Granulated Sugar Successful as Bee Food

In reply to one of Dr. C. C. Miller's Straws, page 219, I believe the Germans are wrong in holding that sugar is deficient as a bee-food, and we are right. Many years ago I used to get late swarms of black bees that were to have been brimstoned, and by uniting two or three of them make a strong colony, putting them on empty combs that contained very little pollen. I waited long enough for them to have but one queen. I killed that queen and gave them an Italian. At the same time I fed them up on good thick granulated-sugar syrup, as I had no honey for them. Then I packed them snugly with chaff. They would winter well, and would rear very little brood until they began to gather pollen from the swamp willows. Then they would rear brood rapidly, and be ready for upper stories as early as other colonies that were wintered on honey. They never showed any signs of disease or spring dwindling.

ILA K. MICHENER.

Climate of Lower British Columbia

Beekeeping is only in its infancy in British Columbia as yet, but seems to have a promising career before it. I might mention that we are in the Fraser Valley, on the south side, about half way between the Fraser and the international boundary, and about thirty-two miles southeast of Vancouver. We have had no snow this past winter, and very little rain. Two cold snaps, each lasting a couple of weeks, one in December and one in January, brought frosty nights with about 16 degrees of frost and brilliant sunny days. The rest of the winter has been very mild and springlike.

Everything is coming forward rapidly now. There is practically only one month in the year when there is no bloom in the gardens, as there are always some late roses in bloom at Christmas. In February the spring bulbs begin to bloom. The bees around here are wintered out of doors in single-walled hives. There is an immense amount of fireweed growing at the edge of the bush about a mile south of us, and the garden raspberries do remarkably well here, growing to a height of ten feet and more in a season. It is so with clover and other blooms. There should be a fair amount of pasturage for bees here.

Langley Prairie, B. C.

H. G. DAVIS.

When is a Colony Strong?

The first thing to do in treating European foul brood by requeening or caging the queen is to make the colony strong. All seem to agree on this. Now the very important question arises, "What is a strong colony?" That is, what strength is necessary for success, and below what success cannot be expected? Ideas as to a strong colony differ widely. This word "strong" in this connection is exceedingly vague. I believe it would be helpful to have all who have had success with this method of treating European foul brood give some way of measuring a colony so all may know what is meant by "strong." Will authorities please tell us?

OUR HOMES

Editor

Who is this uncircumcised Philistine that he should defy the armies of the living God?—I. SAM. 17:26.

Thou comest to me with a sword and with a spear and with a shield; but I come to thee in the name of the Lord of hosts, the God of the armies of Israel, whom thou hast defied . . . that all the earth may know that there is a God in Israel.—I. SAM. 17:45, 46.

Therefore the children of Israel could not stand before their enemies, but turned their backs before their enemies, because they were accursed. And the Lord said, Neither will I be with you any more, except ye destroy the accursed thing from among you.—JOSHUA 7:12.

I suppose most of our readers are familiar with this (in some respects) strange story told in the seventh chapter of Joshua. Under Joshua's administration the children of Israel were successful in their battles. I do not know but success had made them over-confident; but all of a sudden they failed. They were astonished and alarmed, and everybody was wondering what the cause of the trouble was. Their defeat was so disastrous we are told "Joshua rent his clothes and fell to the earth upon his face before the ark of the Lord, he and the elders of Israel, and put dust upon their heads." For once in his life Joshua seems to have complained. He says, "Would to God we had been content to dwell on the other side of Jordan." He urges, in his desperate prayer, that the inhabitants of the land would hear of it, and adds, "What wilt thou do unto thy great name?" But Jehovah rebuked him, and he arose. He says, "Wherefore liest thou upon thy face?" Our text tells us the *cause* of their disastrous defeat. I suppose you know the outcome. There was just one man in the crowd who coveted a fine Babylonish garment, two hundred shekels of silver, and a wedge of gold. Little did he think his greedy and foolish act was going to bring death and defeat to the whole army. Joshua, like a good general, had the culprit held up before the people, and he was punished as the Lord commanded, together with his sons and daughters.

Why do I bring this story in here? Let me tell you. Ever since the organization of the Anti-saloon League I have been wondering and inquiring in my mind *why* we should be thus defeated by the powers of evil. Why should the earnest and fervent prayers of God's people, of the W. C. T. U., of the mothers of our land, of the great and good men of our land, of our college professors, the teachers in our religious institutions, again and again be put to naught? For the past forty years or more I have told you of how the Lord has heard and answered pray-

er in personal work. Again and again has help come when I have been in tight places or crowded into a corner when there seemed no outlet. But when I have prayed that the Goliath of intemperance might be put down in the dust there seemed to be no answer. Men, women, and children—innocent women and children—who were in no way to blame, seemed doomed to suffer, not only for food and clothing, but for lack of education and everything else, and yet we were powerless. The enemy jeered at us, and they laughed us to scorn. They said in derision, "Did you with your few thousands think you could put us out with our millions—not only millions in money, but with the leading men of the nation *right under our thumb?*"

Perhaps that is a little hard and severe; but, dear brother, is it not true that the leaders in politics, even up to the President of the United States, did not *dare* to put a hand on the liquor-traffic? For years and years past our presidents, one after another, in their presidential messages have failed to recognize or suggest a remedy for the giant curse that is keeping down not only the American people but the whole wide world. Even I myself have been tempted *at times* to doubt the statement in holy writ that "there is a God in Israel." Why do we get answers to our prayers in everything *except* in regard to the liquor-traffic? Well, dear friends, of late I have been thinking it over, and I believe I have found the Achan, the "troubler of Israel," with his wedge of gold; and not only that, but *the eyes of the world* seem now to be centering on this Achan and his wedge of gold. I think I can point him out a little plainer by making an extract from a pamphlet just put into my hands, entitled "The Liquor-traffic; its Evils and Cure."* I wish every reader of GLEANINGS would send for this pamphlet. It is about the plainest and clearest showing-up of the liquor-traffic I ever got hold of. Here is the extract I make from it:

The saloon is defended for the revenue it brings to the national government, and no doubt many sincerely believe it to be advantageous to the government. This is palpably untrue. The liquor revenue law was enacted under the administration of Abraham Lincoln as a war measure, and signed by him with the distinct understanding that it would be repealed as soon as the exigency that seemed to justify it had passed. It was my privilege to hear this statement confirmed by Major J. B. Merwin, of Middlefield, Ct., who was present when Mr. Lincoln signed the bill.

* The above pamphlet is published by A. I. Truesdell, 101 West Wood St., Youngstown, O., at 50 cts. per 30 copies; or, say, 5 cts. for one copy.

In the presence of a large audience in Columbus, Ohio, in November, 1913, Major Merwin said in part:

"Mr. Lincoln hesitated in regard to signing that document, and said: 'I would rather lose my right hand than to sign a document that shall perpetuate the liquor traffic; but as soon as the exigencies pass, I will turn my whole attention to the repeal of that document,' and," said Major Merwin, "that was his design; that is what he said to me the last time I spoke to him, and he never would have signed it had he not had the promise of the members of the Senate and of the Judiciary Committees, and of the Military Committee, that it should be repealed at once, after the exigencies had passed."

The exigencies that called the law into being passed more than forty years ago, and during all these years our government has been in guilty partnership with this crime-breeding business.

In an important sense the government assumes control and says: No man may sell liquor without paying for the privilege, and no man may manufacture liquor without paying a stipulated price per gallon; and that there may be no cheating, the government carries the keys to the bonded warehouses and keeps account of all stocks manufactured. It takes this liquor—blood money—not primarily from the liquor-dealer, but—the greater part—from the poor, who earn it by the sweat of their faces and at the cost of shortened lives, diseased bodies, impoverished and unhappy homes, and all the added ills that overtake the victims of the drink habit.

It is a shame and disgrace to the American republic. There is not the semblance of an excuse for the continuation of this guilty partnership. When this liquor revenue question was before the English government some years ago, Hon. Wm. E. Gladstone, "England's grand old man," said: "Gentlemen, you need not give yourselves any trouble whatever about revenue. The question of revenue must not stand in the way of reform. Give me a sober population, not wasting their earnings in strong drink, and I will know where to obtain the revenue."

Russia now furnishes the positive proof that Mr. Gladstone was right—that revenue is increased by eliminating the saloon. Here it is:

LONDON, Jan. 27, 1915.—A dispatch to Reuter's Telegram Company from Petrograd says that Mr. Kharitonoff, controller of the Russian treasury, speaking before the Duma Budget Committee to-day, declared that, owing to the great increase in the national savings due to prohibition, the extraordinary outlay occasioned by the war as yet had caused no great suffering in Russia.

Please notice that when it was proposed to Abraham Lincoln to let the liquor-traffic, for the time being, supply the needed revenue for the war, he said, "I would rather lose my right hand than to sign a document that will perpetuate the liquor-traffic." And this is clearly explained and well understood; but I suppose his assassination prevented his carrying it out as he certainly would have done had he been permitted to live. Now, here is where the *guilt* of our nation comes in. Here is where *Achan* shows himself. From the time of Lincoln down to the present, no one has had the courage to break away from this national crime-breeding partnership. We men who cast our votes are to blame—every one of us. If we did not all know this we *might* all have known of it if we had informed

ourselves. Year after year the unholy alliance has continued. No wonder the author of this pamphlet says it has been a standing "shame and disgrace to the American people." Had Lincoln lived, no doubt he would have had the courage to issue an "emancipation proclamation" against the rum power, exactly as he did against human slavery, and thus might have saved the shame and disgrace that have been hanging over us for the past fifty years. Why did not the kind Father give us *another* Abraham Lincoln who was not *afraid* to face the giant? and shall we not unite in praying God that another Lincoln may come, and come speedily, to our rescue as a people and as a nation?

When the present war broke out there was trouble again. I believe I am not, as a rule, lacking in faith; but Satan kept crowding it on to me, and asking, "Is there *really* a God in Israel? If so, why does he permit this terrible wholesale slaughter of innocent people, including women and children, to go on?" and the war had gone on quite a spell before anybody even suggested that the Achan at the bottom was the liquor-traffic, and that Achan with his *wedge of gold* was the cause of the war, and that God would permit the war to go on as he did in old times until Achan would be pointed out and held up to the light of day—yes, held up to the scorn and indignation of every God-fearing man, woman, and child. Like Goliath, this giant had been parading before the dignitaries of the whole wide world. He kept saying, in the language of Boss Tweed, of former years, "What are you going to do about it?" and we were all afraid. No David appeared with his sling and pebble from the brook to smite him between the eyes. David said in his reply to the braggadocio, "Thou hast defied the armies of the living God;" and the Anti-saloon League, the W. C. T. U., the churches, the Sunday-schools, the Endeavor Societies, the Salvation Army, and good people the wide world over, can back me up when I say this Goliath, since the time of Lincoln, *has* "defied the armies of the living God." When we tried to cut off his sales on Sunday he grumbled and complained, and said we could not do it, and we did not do it. We passed laws, it is true; but this great Goliath managed to put in policemen who could not *see* the open sales on Sunday, even though there were hundreds of them in our great cities with hundreds and *thousands* of customers. He managed to get in policemen who favored his cause, and said, by way of excuse, that "the people" did not *want* the law enforced to the letter. Perhaps the

younger people who read these lines do not remember the notorious "nullification act" when the temperance forces had gotten a law that made a deal "open and shut" on the liquor-traffic, and had put on the lid, as it were, so there was seemingly no escape. Well, some "great men(?)" pretended *they* understood the law to mean what every *schoolboy* knew it did *not* mean. We let it pass because we could not (or *thought* we could not) help ourselves. The great Jehovah of former times seemed to have turned his face from us. *He* apparently did not see or did not hear; and we stupid mortals could not understand that he was just letting us go until we were *forced* to learn the lesson he was trying to teach us.

There is just *now* one ray of light coming; in fact, the extract I have made above indicates it. To the surprise of almost every good man and woman on the face of the earth, Russia—yes, poor stupid heathen Russia (as we were wont to call her here in the United States) all at once discovered that a *drunken nation* or a nation of drunkards is no match for a nation of sober people; and the Czar of Russia, without any preamble, and without consulting anybody, put on the lid, as we express it in the United States, and, without any warning, kicked out this liquor Achan with his shekels of *silver* and wedge of *gold*. He did not stop to argue about *revenue*; and, to the surprise of the liquor-soaked people of that great nation, they began to feel *better* and *happier* right away; in fact, like the poor demoniac who dwelt among the tombs, all at once they became "clothed and in their right mind."

Abundant figures have been given to show that if this reform keeps on for only a short time, more lives will be *saved* than have been lost in the war. It has been a terrible lesson to us all, God knows; but as you go back over the ground I have covered in this Home paper does it not seem probable that this terrible war was the only thing that *would* arouse our people and help them to consider the enormity of our guilt in permitting this thing to go on as we have done?

While I write, the United States is considering whether it will be safe to follow the example of Russia. The separate states, one after another, have taken it up and become "white" and clean at an unprecedented rate. In another place I have told you how Florida has just defeated the giant, and has come out in plain and unmistakable terms for freedom from the tyrant. Ohio
